WHEN cuttings of the various kinds of bedding *Pelargoniums* can be obtained as early as the end of July or beginning of August, they may be inserted in ordinary garden soil in a sunny situation in the open air, and will only require to be made firm in the soil, watered occasionally, and kept free from weeds, &c., when they will generally be found to root freely, and will be found fit for potting up by the beginning of October. In many instances, however, it has been found difficult, during the present season, to obtain cuttings sufficiently early to do this, and it is now too late to insert cuttings of these plants in the open borders. Let them, however, be inserted in pots some 4 or 5 inches in diameter, in pans, or in boxes, and placed on cinder ashes in frames or pits, without, however, placing the lights over them as yet, but having them in readiness to be applied whenever heavy rainfall or depression of temperature renders this necessary. It will, doubtless, also, in many instances be found necessary to pot up a considerable number of zonal and other *Pelargoniums* from the beds, and, as such plants have this season made comparatively little growth, they will, consequently, be found to be in good condition for this purpose. As regards the more tender or, at least, less easily increased variegated and tricolor sorts, it is not advisable during any season to trust altogether to the autumn-struck plants; but, in addition, such a number as may be required of the smaller plants from the beds should be lifted and potted before they have been injured by frost. These plants will generally make fine healthy material for furnishing the beds during the following season, supplemented by the smaller plants which have been struck during the present autumn. In the formation of ribbon lines, however, it is generally desirable to use autumn-struck plants of the previous season, in order to secure, as far as possible, uniformity of size. Carpet beds have this season succeeded well, and are now in great beauty, and this style of decoration appears to increase in public favour. To be really effective, however, such beds should have their divisional lines kept well defined by constant pinching or stopping, and this involves but little labour, and is easier accomplished than might at first sight appear to be the case. The various species of *Alternanthera* are among the most useful plants used in this style of ornamentation; but owing, probably, to some peculiarity of the season, some of the species, such as *amabilis* and *paronychioides*, although they have grown well, and have long ago quite covered the soil, are only now beginning to assume the brilliant tints for which they are so very remarkable when grown in the open air, but, their foliage, up to nearly the present time, has been almost quite green. The beautiful species known as *A. amoena* has, however, been an exception to this state of things, having, throughout the season, been as brilliant as usual. The present is a suitable time to study carefully the arrangement of the flower garden, &c.; and, if any desirable alterations or improvements suggest themselves, a note should be made of the same at once, and this should be attended to and carried out at the proper time. Observe, also, the effect produced by the blending of the various shades of colour in flowers and foliage, as much can frequently be done in this way without either additional labour or expense; and the effect produced by the admixture of certain flowering and fine-foliaged plants must be seen to be sufficiently appreciated, such as

that of some of the finest blue Lobelias, or the *Viola cornuta*, with the finest silver-margined or gold and silver tricolor *Pelargoniums*, &c.; or that of the late Mr. Beaton's celebrated shot-silk bed, produced by the admixture of Mangles's variegated *Pelargonium* and *Verbena venosa*. Make notes, also, of the probable number of the various sorts of plants required to carry out the contemplated arrangements of the following season, allowing, at the same time a wide margin for probable contingencies or losses. If not already done, finish at once the planting out of Carnations and Pinks, bearing in mind that, if this is done now, they are more likely to lace well than when planted in spring. Attend carefully to the various routine operations connected with the pleasure grounds. On account of the long-continued draught, mowing will be but little required; while the broom will be found to be in greater requisition than ever, as the "sere and yellow leaf" already litters the lawns and walks, and must, of course, be removed every morning if order and neatness are to be preserved.—P. GRIEVE, *Culford, Burg St. Edmunds*.

Roses.

The Manetti forms an excellent stock for many kinds of Roses, but it does not suit *Maréchal Niel*, on heavy soils so well as the Briar. Hybrid Perpetuals, however, do well on it, and I have some very good pot Roses on it. In all cases I have found the Manetti stock better suited for light soils than for heavy ones. I have *Gloire de Dijon* in pots, budded on the Briar, and then *Maréchal Niel* budded on that; the *Maréchal* thus treated, forms a beautiful bush, and flowers freely. From this union I have been cutting good blooms all through the season, and I can thoroughly recommend *Maréchal Niel* as a pot Rose, "worked" in this manner. After trying many stocks, I have found the Briar to be the best for general use; in the case of the *Maréchal*, provided care is taken not to prune him in too freely, a good succession of beautiful yellow Roses may be kept up all through the season. Continue to give plenty of water to Roses in general, out of doors, while the weather is so dry; where they are planted in shrubberies or close to plantations, this is especially necessary, as the surrounding vegetation deprives them of moisture, rendering them unable to make flowering wood for the following season. Dust a little sulphur on all trees on which mildew makes its appearance.—H. G.

Indoor Plant Department.

The most attractive flowering plants in conservatories at present are the different varieties of *Lilium speciosum*, *Vallota purpurea*, the good old, but often neglected, *Roechea falcata*, and the still rarer *Griffithia hyacinthina*. If these things are grown well in sufficient quantities, intermixed with the general occupants of the conservatory, they will keep up a display for five or six weeks, especially if a portion of the stock is retarded by being placed where it will receive comparatively little sun and abundance of air. See that all these things receive regular attention as regards water, as any omission in this matter will make short work of the blooms, and in the case of Lilies will destroy the foliage. Keep a good look-out for that most destructive of all plant pests—red spider. If allowed to establish itself even thus late in the year, it does irreparable damage for another season, by premature destruction of the foliage of any plant which it happens to attack. Chrysanthemums will now require rich and copious waterings twice a-day, if the weather continues dry, and their pots filled with roots, as they ought to be by this time. Syringe them overhead in the evenings of bright days; if this is attended to they rarely get infested with greenfly. Pay every attention to winter-flowering plants, such as *Cinerarias*, *Primulas*, *Euphorbias*, *Peinsettias*, *Bouvardias*, *Salvias*, &c.; the more stent and robust these plants are now, the better they will bloom, provided they are well ripened. If *Peinsettias* and *Euphorbia jacquiniædora* have been placed in a cooler situation during the present month than they have previously occupied, they should be removed from such a position before the nights become too cold, or both leaves and roots will suffer, which will be fatal to their blooming. All the occupants of the stove and intermediate house that have been used for conservatory decoration during summer months will soon have to be removed to warmer quarters, otherwise they will be injured. *Achimenes*, *Tydas*, *Gesneras*, and *Gloxinias*, should soon be dried off and put to rest, placing them in a situation free from damp, where the temperature will not get lower than 50°, otherwise they are in danger of rotting. *Encharis amazonica* will soon require to be placed in a warmer temperature than that of the conservatory, or it will suffer. If a late sowing of Asters has been made, with a view to their being potted for conservatory decoration when coming into flower about the end of next month, provision should be made for covering the bed with loose lights to protect them. See that such things as *Acacias* and *Cytisus* are fully exposed to the sun in an open situation, for the better they get hardened out of doors the more satisfactory will be their blooming. Put in another batch of

Hydrangea cuttings; these will bloom late in the summer if kept cool during the spring, and will come in when flowering plants are scarce. Attend well to herbaceous *Calceolarias*, so as to get the plants stout and strong; by this means they get so much better through the winter. Conservatory climbers should now be regulated, reducing freely all excessive growth, so as to allow of its being sufficiently thin for each plant to get thoroughly ripened before the short days are upon us.

Orchids.

These generally require less shade and water at this than at other seasons, and now is a good time to overhaul and re-arrange the entire collection, after having first cleaned the glass, wood-work, and benches. It is particularly desirable that the glass should be kept clean, as all the light it is possible to obtain during the winter months in our climate is small in proportion to what is desirable for Orchids, and to which nearly all of them are subjected in their native habitats. Abundance of light and air exert a wonderful influence in ripening up the growths and pseudo-bulbs; and one of the consequences of this is that the flowers produced are not only larger and of better substance than they otherwise would be, but also much brighter in colour. *Calanthes* should have plenty of tepid water at the root, and be kept near the glass in a warm equable temperature. Their foliage is very apt to become spotted and disfigured unless carefully protected from cold draughts. Few Orchids are more easily grown, or yield better results than these, but even slightly irregular treatment with regard to either heat or moisture will ruin them for a season at least. *Pleiones* do best on shelves near the glass, whence they can, however, be brought down nearer the eye when in bloom. The surface of the pots should be carefully examined for slugs, woodlice, and other pests of that kind, the best time to do this being at night, with a bull's-eye lantern. During the daytime they hide under the pots or among the compost. Slugs are frequently very troublesome, as they seem to prefer the fresh succulent flower-spikes to leaves, and in this way they soon commit a great amount of damage unless constantly kept in check.—E. W. BUREIDGE.

Indoor Fruit Department.

We have now arrived at the kindest growing part of the season as regards Pines, so that little trouble or anxiety is necessary in that direction. Fruit will colour freely by the application of abundance of light and air, and the withholding of humidity. Swelling fruit requires applications of tepid clear manure-water, kindly applications in suitable weather of atmospheric humidity, and the interior atmosphere charged with ammonia. Give air freely by day, and use no shading. From plants now showing flower, atmospheric moisture should be withheld till after they have bloomed, after which apply it freely. Plants intended to show fruit in October and November should now be aired freely, night and day, humidity being withheld, and root waterings not too freely applied; but never let them be famished for lack of water, or they will produce weak and abortive fruit. Plants intended to rest and harden in October and November for starting into fruit in December and January next, should have every encouragement in the way of applications of tepid manure-water at the root. Succession plants will have arrived at the very best part of their growing season, and will require previous instructions to be fully carried out, and the night atmosphere reduced somewhat as the days decrease. The application of abundance of air in maintaining healthiness and a robust growth, abundance of heat, air, and humidity, and no shading, are sure to ensure all that can be wished. Suckers, of course, should be taken off and potted at once; to grow on, without less of time or check, is the only way to succeed in always having at command fine healthy plants, in every stage, at all seasons. The foliage of the Vines in the early house will now be getting ripe and falling, and the Vines may be pruned and dressed for forcing in November. Vines in pots for early forcing may be placed out of doors, and the pots should be laid on their sides in very wet weather, to prevent the roots from being too much drenched before they are taken into the forcing houses. Late Vineries, wherein Grapes are ripening, should have plenty of air in favourable weather. All outside borders should, if possible, be covered with lights, or wooden shutters, to keep them dry, before the cold autumn rains chill the roots. The crops of Peaches and Nectarines in the late houses will now be nearly all ripe, and when the fruit is all gathered the trees must be well syringed with soft-soap, or Gishurst compound, to prevent the brown scale from attacking the wood. The trees in the early houses which have ripened their wood may now have the foliage brushed off with a new broom, and the wood loosened from the trellis. Now is a good time to get a store of turfy loam stacked up to keep it dry, should the planting of Peach and Nectarine trees be decided on in October or November, either for

out-of-doors or in the houses. Peach and Nectarine trees do best in good fresh turfy loam without the addition of manure of any kind in the soil, as it only makes them produce strong watery shoots, which never ripen well. Of all things to be avoided in the soil is old rotten tan, vegetable mould, or any material containing pieces of rotten sticks, for they all breed Fungi; and, when they attack the roots of Peach trees they are soon totally unproductive. The roots of Vines are likewise liable to be attacked by them, and the failure in crops of Grapes from root Fungi is often attributed to some other cause. When the fruit is all gathered from the trees in pots in orchard houses, the pots may be placed out of doors, and, if they are plunged in some warm corner, it will save some watering. The late crops of Peaches and Nectarines, Plums, and so on, will want a thorough watering now to swell the fruit. In cool orchard houses some of the late varieties of Peaches and Plums can be kept later than those on the walls or open borders. Too much syringing will now be injurious to late Cucumber plants, as the sun's heat will be gradually declining. If thrips put in an appearance, remove the infested leaves, which are generally the old ones, and fumigate two or three times, at intervals of four or five days, till these pests are conquered. Mildew will sometimes attack Cucumbers in frames or damp pits, and flowers of sulphur must be applied till it disappears. The plants intended for the winter supply must now be planted in the house or pit as early in the month as possible, on purpose to get them strong before the short days set in.

Hardy Fruit.

One of the most useful fruits in the garden is the autumnal Raspberry. It is one of those fruits which emphatically pay for culture; but, as often seen, they are hardly worth a moment's attention. To bear fine luscious fruit the plants must have good preparation and proper treatment. By the first I mean a deep rich soil with a foot of farm-yard manure incorporated with it. The strain upon plant life reaches its maximum in autumn; the sun does its best to exhaust as well as mature, and, unless the roots are duly fortified, the plants will be likely to succumb to its exhausting, as well as yield to its consolidating, force; but, with depth of root-run, the plants flourish, for depth of tilth supplies the needs of plant-food and water. These require to be well supplied when plants have not only to ripen but grow, and bear a full crop of juicy fruit, such as Raspberries in the autumn. Having duly prepared for the wants of the plants, the next point is to duly qualify the plants themselves for their work. The old name of Double-bearing has proved most mischievous, inasmuch as it has led the cultivator to expect two crops a year from his Raspberries; and so he may, if size and quality are no object; but if they are, then he must take but one crop only. As soon as this is gathered, which may not be till the middle or end of November, cut the plants level with the ground, leave no wood, old or new; top dress the stools with rich manure, and leave all bare till the spring. When the young shoots appear, select from three to nine, according to their size, strength, distance apart, &c.; and if the growth is moderate and the garden tolerably well sheltered, allow them to grow as they choose, without tying; but if not, and there is danger of breakage from wind, then tie loosely for the sake of safety, and so that sun and air may freely reach all sides of the young shoots. Canes thus treated will soon break into branchlets, fruiting all over, and from the middle of September, in suitable localities, till caught by the frost, excellent Raspberries may be gathered. The active vital force of the plant is thus concentrated, as it ought to be, into its autumnal crop, and the crop is good accordingly. Should dry weather ensue, water copiously, for the Raspberry likes water, and, if seasoned with guano, or other manure in solution, better still, for the plant is a gross feeder, especially when laden with fruit. Cultivators are much indebted to Mr. Rivers, of Sawbridgeworth, for improved varieties of these autumnal fruiting Raspberries. His autumn Black and large Orange are valuable plants; the first, however, does not produce many suckers, but comes pretty true from seed. The October Red and Yellow are likewise great improvements on the old Double-bearing Raspberry, and have the blood and much of the quality in them of the well-known and justly prized Fastolf. Cultivators who have not these useful Raspberries, should prepare a piece of ground at once, and plant early in November, cutting the canes in February or March, and thus lay the foundation for fruit next autumn.—D. T. FISH.

The Kitchen Garden.

Now is the time to push on the main crops of Celery with frequent soakings of liquid manure; as, during the longer cooler nights of approaching autumn, the growth will be rapid and crisp if well fed. All early crops should now have a final flooding of water, and be earthed up, pressing the soil firmly round the plants; but, of course,

not burying the hearts. Referring, for a moment, to the question of earthing-up Celery, my own experience would lead me to recommend this to be done, as far as possible, at one operation only. I never could see that earthing-up added anything to its growth, but it certainly is a bar to the free application of water, so necessary to the full development of a marsh plant like Celery. Rather than recommend the plan of earthing-up by small instalments, I should advise heavy mulchings of short manure amongst the plants to check evaporation during the growing season, and at the proper time, of course selecting a dry day, earthing up to the requisite height at once. Now that the weather has apparently set in dry again, late Peas must be well supplied with water to assist them in setting and swelling their crops. Prepare a bed for French Beans in any spare pit or frame; if a little bottom-heat can be provided by working up an exhausted hot-bed with a little fresh stable dung so much the better. This sowing will probably come in usefully during the autumn, after those in the open air are cut off by frost; dwarf early kinds, like Osborn's Forcing, or Newington Wonder, are best for this crop. Plant them in rows 15 inches apart, and the Beans should be about 3 or 4 inches apart in the rows. Dast young Cabbage plants freely with soot or lime to banish the fly which will, perhaps, be troublesome. If the plants are at all thick in the seed-bed, thin them out, and transplant the thinnings about 3 inches apart, so that all may grow up strong and short in the leg. Look Tomatoes over frequently to remove all superfluous growths, and to gather the ripe fruit. A good soaking of water, if the weather continues dry, will be beneficial, at the same time keeping them closely mulched. Sow French Breakfast, White and Red Turnip, and the Black Spanish Radishes in light rich soil. Make another sowing of Brown Cos and other hardy kinds of Lettuce for winter on a south border. After this date Cauliflowers will be better sown thinly under glass, those plants just coming up in the open border must have frequent dustings with lime and soot. Sow Chervil for the last time, and do not forget to have a box or two filled to take under cover when bad weather comes. Transplant a good breadth of Lettuce and Endive for winter, and there is no occasion to plant all in one aspect, but, rather the reverse, so as to be prepared for any weather. Keep up the necessary successions of small salading, according to the demand. This is the best time to gather the various kinds of vegetables for pickling; and also for drying such herbs as Basil, Marjoram, &c.; they may be dried well in the Vineries, laid on sheets of paper under the shade of the Vines, to be afterwards kept in wide-mouthed bottles, closely corked. Thin late sown Turnips to about a foot apart. Maintain a loose friable surface among growing crops by frequent stirring. Weeds are much easier destroyed when small; therefore keep the hoe going freely; every inch of bare surface should be loosened up.—E. HORDAY.

Moles in Cutting Beds.—Of all garden pests, I know of none that can equal the mole in the production of annoyance. It is not so much a destructive animal as a nuisance, and as for the good it is said to do, if its food consists mainly of the harmless earth-worms, then I question its usefulness in any degree. If one of them starts a run amongst a plot of Potatoes, Cabbages, or other established vegetables, it cannot do much harm, except when very dry weather prevails, and then the soil is drained rather too freely; but when one gets in a seed-bed or amongst flowers, or, as one did with me the other night, amongst a large bed of Pansy cuttings, it does a deal of mischief. When in a nice loose moist soil, such as my cutting bed, it runs hither and thither with the most disastrous results; and the work of days is in an hour almost entirely destroyed. In this special case I had just replaced the cuttings, and made all ship-shape, when my sable friend commenced working again, and I at once dug him out. In such cases it is no good to attempt trapping moles. The best mode of dealing with them is to have a small fork in hand, and watch; then seize the favourable moment, and give the subterranean worker a quick lift out of the ground.—A. D.

A Valuable Recipe.—The *Journal of Chemistry* publishes a recipe for the destruction of insects, which, if it be one-half as efficacious as it is stated to be, will prove invaluable. Hot alum water is a recent suggestion as an insecticide. It will destroy red and black ants, cockroaches, spiders, chintz bugs, and all the crawling pests which infest our houses. Take two pounds of alum and dissolve it in three or four quarts of boiling water; let it stand on the fire till the alum disappears; apply it with a brush, while nearly boiling hot, to every joint and crevice in your closets, bedsteads, pantry-shelves, and the like. Brush the crevices in the floor of the skirting or mop boards, if you suspect that they harbour vermin. If, in white-washing a ceiling, plenty of alum is added to the lime, it will also serve to keep insects at a distance. Cockroaches will flee the paint which has been washed in cool alum water.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

THE ROSES OF 1874.

By S. REYNOLDS HOLE.

(Continued from p. 165.)

IN Connemara, with the great Diamond Mountain, in all its solemn majestic dignity, before me, as I look through the window and over the Fuchsias of Casson's tidy little inn at Letterfrack, in the land of the Shamrock, sitting down to write about the Rose—going back in thought upon that telegraph of the imagination, which makes the operations of the electric wires seem halt and hampered, through the magnificent scenery of the Twelve Pins, by Lough Corrib to Galway; and thence, straight as a line, through Ireland, over the sea (with a shudder as I recall the exhibition of sickly men which I saw six days ago upon the deck of the steamer Connaught!) to Holyhead, home, and the Roses! And, though I have seen so much that is beautiful, and so little that is horticultural,* how distinctly, in all their vivid loveliness, those Roses gleam! for every true gardener carries with him, as every true lover the miniature of his absent love, a likeness of his garden—painted, not merely photographed, upon memory, in form and colouring complete. Yes, I can see my Rose trees just as I left them, and can tell my readers of their recent failure or success as accurately as though I took, like Alphonse Karr, an actual tour round my garden, and wrote, like Gluck, out of doors.† Returning, accordingly, to my alphabetical review of the Roses, as I have seen them in my own garden and elsewhere in the summer of 1874, and recurring to the letter G, I would observe that only Dijon has maintained its Glory. The Glory of Bordeaux has not been La Rose in the garden, whatever it may be among the Vines. The Glory of Santenay, and of Vitry also, have paled their ineffectual fire. Henri Ledechaux has been very good with me, and is now an established favourite; and Horace Vernet has displayed a variety of military and sanguinary scarlet and crimson tints, which would have gladdened his namesake's heart. John Hopper has shown, by his dusty and disordered raiment (I mean by the mildew on his crumpled leaves), that he has had a close tussle with John Frost, but he has "come up smiling," in pugilistic phrase, and with victory written upon his handsome face. Never, since I gave half-a-guinea for Jules Margottin (it must be twenty years ago), have I seen that Rose so dwindled and discomfited, but it must still be retained in every collection as an excellent garden Rose. La Belle Lyonnaise made her *début* a little too late, and it, as the Irishman remarked, she had only been born before her mother, she would have made a sensation. She has, nevertheless, many charms of her own, though we may not notice them, when we meet her side by side with her mamma—Gloire de Dijon; and, where the Rosarian is rich in walls, the Beauty of Lyons should find a place. And now for the Rose, which must, I think, claim the premier prize for the quantity and quality of its blooms, in this untoward season, and which Guillot, fils, had the good fortune to send out, in the year 1867, and the good taste, as a true Frenchman, to name La France. Reader, do you remember how the slim delicate "swells" of Rotten Row distinguished themselves, half froze and half starved, in the trenches before Sebastapol, and how some said, when the war-news reached us, "There's something in 'blood' after all!" So has it proved with this high-bred beauty. She has stood cold and heat, to which the luxuriant and obese have succumbed, and has emerged from adversities (so may La France herself come forth from her trials) with a sweet and graceful beauty. I must next select from the L division, as one of the best Roses of the year, Louis Van Houtte, rightly named after the great

florist of Ghent, and admirable as a well-shaped dark crimson Rose. We have to thank Lacharme for this acquisition. And now we must take off our hats to a procession of ladies—*mesdames et mesdemoiselles*—glowing, radiant, as these who wait upon our Queen at a drawing-room; but in this superior, that every blush is real, that upon their cheeks there is neither rouge nor pearl-powder, and that the gloss upon their foliage knows no oil. The first I would select (still following the principle of "The A B C Guide") is Madame Bernard, like La Belle Lyonnaise, a daughter of Gloire de Dijon, but distinct in its rich Apricot colouring. It was sent to me by my friend, Mr. Prince, of Oxford, and grows luxuriantly upon the seedling Briar. Mesdames Ball, Bravy, Caillat, Crapelet, and Charles Wood, have resented the rude insolence of Mr. Vernal Frost, either by declining to come out altogether, or by publicly wearing the shabbiest dresses in their wardrobe—raiment much resembling that of the individual referred to in the great epic of "The House that Jack built," who took advantage of the heroine's forlorn condition for osculatory advances, which led to matrimony. Not one of them have I seen in her Sunday clothes; but it has not been so with all the sisterhood. Just as you may see in this humid island fair ladies come ashore with their lords from fishing, after they have been overtaken by drenching showers, or exposed to cold boisterous winds, looking all the bonnier and brighter for the storm, so Madame Clemence Joigneaux, whose praises I have so often sung, has bloomed this season, as though May had been all that those gay deceivers, the old English poets, describe it—shepherds flirting, in silk stockings and pumps, to shepherdesses in book muslin and blue ribbons, by purling streams and under cloudless skies, in a climate where catarrhs were unknown. Were I permitted to grow but half-a-dozen Roses, this hardy, honest, buxom beauty, whom age cannot wither, should certainly be one of the six; and, were I called upon to name the remaining quintette, I should elect Gloire de Dijon (for its semperflorant qualities), the Baroness, La France, Marie Beaumann, and Maréchal Niel. Resuming our "dream of fair women," I have been much delighted to see a Rose, which has almost gone out of cultivation, because, owing to a delicate constitution, it is so seldom realised, blooming beautifully in this untoward season—I mean Madame Furtado, which has been one of the best in my rosarium, growing upon the seedling Briar. Concerning this stock, as a nurse and mother of Roses, I promised and hoped, having used it largely, to make this summer a comprehensive statement, but the severity of the weather has rendered it impossible to gauge or compare its capabilities. I still retain my confidence in its superiority, and I believe that Rose trees, thus established, will prove to be the most enduring of all. The process is slow; and, should the nurserymen adopt it, they must raise the price of their Rose trees, but these will be in the end much cheaper to the purchaser than the standards and half-standards which, violently pulled out of hedgerows, rarely live long in the garden. As to the fair Madame Lacharme, with her delicate complexion, I am afraid that our ordinary summers will be too severe for her (as for Miss Ingram and many other of our most charming Roses), but in one of those exceptional and glorious seasons, when there is no winter in our spring, and when the heat of our summer is tempered by refreshing showers, I shall expect to see a vision of beauty in the Rose called Madame Lacharme. The lovely Madame Therese Levet has suffered severely, and Madame Victor Verdier also, but her daughter, Mademoiselle Eugenie Verdier, has realised most of her charms; and another young lady, Mademoiselle Marguerite Dombrain, has sustained small hurt from the storm. Marguerite de St. Amand, though much reduced in her proportions, has been a most interesting invalid; and last, but not least, of the ladies, Marquise de Castellane and Marie Beaumann have both been excellent. Maréchal Niel, upon the border and upon walls looking east, has been unusually grand and glowing, and brave old Maréchal Vaillant has once more shown himself worthy of his ancient fame. Nardy Frères and Paul Neron have both profitted from their "robust habit," and have given us substantial proof of it. A large bed of the latter variety is invaluable for supplying cut Roses. Sénateur Vaisse, like some other members of Parliament, has not distinguished himself

* I may have something to say hereafter of the gardens which I saw in Ireland.

† It is said that Gluck had his piano carried into the most picturesque spot he could find; and there, with waving trees, and wild flowers, and singing birds (and, softly be it spoken, a bottle of Champagne!) around him, composed his beautiful melodies.

this session; nor, as I look through my list to its close, do I see any other Rose, except Xavier Olibo, which has not evinced melancholy evidence of vernal and æstival adversities.

So we will leave our old favourites, with a sigh and a tear, and refresh ourselves with a look at the new Roses.

(To be continued.)

THE DECAY AND SPOILIATION OF THE CRYSTAL PALACE GARDENS.

MOVED by Mr. Scott Russell's report we visited the Crystal Palace gardens during the past week with a view of examining their condition. We found the ruin appalling and apparently beyond repair. In its best days there was a good deal of the Palace gardens which no one with any artistic insight into landscape gardening could admire. All the geometrical gardening below the upper terrace was a gigantic mistake, resulting from an unfortunate desire to outrival the stony glories of Versailles, and the many arid triumphs of Continental gardens. The great fountains and fountain-basins cost hundreds of thousands of pounds, and, combined with such barbarisms as water temples and Rose temples, too high for the tallest Roses to scramble over, made hideous what might have been easily made the finest garden-landscape in England. At this moment much of this part of the grounds presents a most hideous ruin. The enormous and ugly fountain-lakes with their miles of huge iron piping, like sea-serpents stranded in muddy waters, are now rendered more offensive than ever by the foul-looking water having fallen low from the banks, and by the almost unaccountable ruin of the water temples and colonnades. The enormous cascades have not played for eleven years; a fitting result of the waste of precious means in such ignoble masonry. In its best days all this showy water tossing had not as much beauty as a mountain streamlet; now it is the most lamentable sight we have ever witnessed in a public garden. We question very much if any reader would or could imagine the disgrace to which these vast works have come without personally examining them. Let us turn aside and seek for a little relief in those parts of the garden devoted to trees and flowers. In what might be a quiet verdant spot, a board announces—"To the stalactite cave: admission, one penny." On entering, the "stalactites" were found to be white-washed, and most effectively whitewashed! The large collection of vulgar noisy swings, &c., &c., which occupy a considerable space in what might be a very charming part of the grounds, is in good keeping with this whitewashed stalactite cave. But is the garden of the "People's Palace" at Sydenham the place for exhibiting the commonest features of Bartholomew or Donnybrook fairs? Surely every part of these noble grounds might be occupied with something much more attractive and beautiful to the very commonest people than these wretched toy railways, &c., and not offensive to any. Such features are sufficient to spoil even a decent tea-garden, but the worst has yet to be told. The one thing for which those with feeling for the beautiful in landscape gardening always felt grateful to Paxton, was the belt of beautiful plantation that so gracefully cut off the grounds from the chimney-pots around. This plantation was formed at a cost of many thousands of pounds, and contained specimens of nearly all that was beautiful in the trees and shrubs of northern and temperate regions; when wearied with the crater-like dreariness of the great stony region, one could lift the eye to this splendid belt of vegetation, and therein find rest. Often, when tired of the more showy attractions of the Palace, we have walked round this noble plantation, admiring tree after tree, of many of which no such good specimens were elsewhere to be seen about London. So careful were the original projectors of the Crystal Palace to secure that first principle in landscape gardening—a quiet boundary to frame their garden picture—that they bought a great deal of the land around, and laid it out in large well-planted villa gardens, with a view of preventing, as far as possible, all intrusion of houses on their paradise. Then the noble plantation above-mentioned was formed, and so well, that for many years it was the chief garden charm of the place. *This plantation has been almost*

entirely cut down, and long lines of red villas stare into the garden in its place. The consequence is, that the beauty and repose of the garden landscape is destroyed. And to what end? For the gain of about £1,200 a year (the ground rent of these villas) the grounds have sustained a loss which no money can repair. The present expenses of the Company amount to £109,000 a year, and for a miserable gain of little more than a thousand a year, the Company has damaged the gardens in the most effective way possible. One unhappily sees many instances of poor design in public gardens, and of noble surfaces of garden-ground frittered away to unmeaning and tormenting ends, like the gardens at South Kensington, but of blind destructiveness or rank *bêtise* in the direction of a great public garden, we have never witnessed such an instance. As for the indoor collections, the great fire and various other causes have long ruined these; but, before it took place, the fine collection of Camellias and Oranges, and the many superb plants purchased from the Loddiges, had, for the most part, perished from sheer neglect.

Lilium pomponium.—As far as my observations go, the true *Lilium pomponium* of Grenier and Godron, is not known to English cultivators, although the name occurs in most nurserymen's catalogues. There seems to be much confusion between *L. pomponium* and *L. pyrenaicum*, the latter species being almost invariably sold by nurserymen for *pomponium*. In June, 1872, I dug up two roots of a Lily in the Maritime Alps, which have flowered with me this year, and are the true *Lilium pomponium* of Linnaeus, and of Grenier and Godron. It is a much handsomer species than the plant generally cultivated under the name, which is merely a red variety of *L. pyrenaicum*. *L. pomponium* of the Maritime Alps is easily distinguished from *L. pyrenaicum*, by its strictly linear and very narrow leaves, which have no tendency to be lanceolate. The flowers are considerably larger, and instead of being dull red in colour, are of a clear scarlet, approaching *Chalcedonicum* in size and colour, though a trifle darker; the bases of the perianth segments are covered with warty protuberances, and the anthers are disproportionately large, and quite twice the size of those of *L. pyrenaicum*. *L. pomponium* seems to be tolerably frequent in the Maritime Alps, though confined to a limited range in the district surrounding Nice. *L. pyrenaicum* has, I believe, not been found west of the Pyrenees, excepting in the Devonshire habitat, near South Molton, where I observed it in 1852, apparently wild. I still have it in cultivation, and it differs slightly in habit from the species obtained in the Pyrenees.—GEORGE MAW.

Exhibiting Roses.—During the last few weeks a spirited controversy has been carried on in the horticultural and gardening papers as to the best way of exhibiting Roses. The gauntlet was thrown down by the redoubtable Mr. William Paul, who exhibited a collection of 6,000 trusses in groups, and arranged in geometrical patterns according to colours. Under certain conditions we can see no objection to a great Rose grower exhibiting the superabundant riches of his gardens in this way; and in our opinion it is certainly an advance on the usual way of exhibiting the same masses of flowers in rectangular green boxes margined with ragged Moss. Such a blaze of symmetrical beauty reminded one of a royal night at the Opera in comparison with a "Foresters' Day" at the Crystal Palace, or the "Hallelujah Chorus" after an energetic German band. When masses are at hand who can object to their being arranged in pleasing forms? Geometrical patterns are not objected to in flower beds, or Roses in wreaths, and in both of these the individual forms of the flowers are lost. We incline to the opinion that both disputants are more or less in the right, for whilst Roses are perfectly lovely when arranged in devices or scrolls, they are equally (or still more) lovely when isolated. But because the isolated face of one of Raphael's heavenly Madonnas transfixes us by its unearthly beauty, is that any reason why we should rip up Michael Angelo's "Last Judgment"? Because we are charmed by Mozart's "Minuet," are we not to be spellbound by the involved beauties of Beethoven's "Pastoral Symphony"? There can be no doubt that, to æsthetically enjoy Roses the flowers should be isolated, so that every quality of the bloom is made manifest; and to most Rosarians we imagine that ten perfect flowers would be more satisfying than 10,000. We have had more mental enjoyment whilst contemplating three or four perfect Roses on our own table than in all the "Rose shows" at South Kensington. One is like classical chamber music, the other like a contest of brass bands at the Crystal Palace. We must take Roses for their own value, and they are never so exquisite as when seen singly in slight transparent flower-glasses, as used for the table; but when they are wanted in masses, pray let us give a preference to pleasant curved lines over square deal boxes.—W. G. S., in *Floral Magazine*.

NOTES OF THE WEEK.

— WE are at a loss to understand the motives which prevented the fruit committee at Kensington from giving a certificate to the excellent and distinct Melon brought from Africa by Sir S. Baker, and grown by Mr. Groom, at Hienham Hall Gardens, particularly as we know not a few of the best judges on the committee pronounced the Melon the best flavoured they had ever tasted. The stated reason was that the fruit was "rough and coarse," to which we wholly demur. If increase of size is accompanied by deficiency of flavour in a fruit than it may be termed "coarse," but when the flavour is actually better, such a decision seems a puerile one. Perhaps the committee do not like such a deviation from the shape of the nice round little Melons they are accustomed to. To us, however, it seemed a much handsomer fruit than the common type.

— M. JEAN SISLEY writes to say that the great Rose show, which was to have taken place at Lyons in July last, and which was postponed on account of the hail storm that occurred on the 21st of June, will take place at the same time as the general exhibition of the Association Horticole Lyonnaise, which will be held on the 17th, 18th, 19th, and 20th of September, in the park at Lyons. A special jury of English, Belgian, Swiss, and Parisian Rosarians will judge the new Roses, which, it is expected, will be numerous and fine.

— WE are informed that M. Max Leichtlin has just returned from Montenegro, and that he has brought with him a large quantity of the purple Lily (*L. Cattanei* or *L. Martagon dalmaticum*). He is also in possession of supplies of the famous *Tulipa Greigii*, one of the most remarkable hardy plants ever introduced, and of a Sparaxis-like Cape bulb, the *Fresia Leichtliniana* (Klatt.), with yellow and orange-coloured flowers deliciously scented, all desirable plants, which we may soon expect to see in our leading nurserymen's lists.

— AT last, in order to meet the requirements of the market gardeners and the salesmen at Covent Garden Market, his Grace the Duke of Bedford has given instructions to Messrs Cubitt, builders and contractors, to erect a roofing over the south wing, similar to that which covers the vegetable market on the north side. During the past week workmen have been engaged in erecting a large trolley for the purpose of carrying out the work. This may save a small portion of the busy multitude of porters and others from the heavy winter rains. London has now some of the finest markets in the world: when shall we see a fruit, vegetable, and flower market worthy of it?

— THE Hollyhock disease, produced by the attacks of *Puccinia malvacearum*, has, according to the *Florist*, been successfully grappled with by Messrs. Downie, Laird, & Laing, by alternate applications of Gishurst compound and flowers of sulphur. The Gishurst was first applied at the strength of a shilling box, to 12 gallons of water, followed the next day or so by a good syringing, and subsequent application of sulphur, through one of Pooley's distributors. These two distinct operations were performed twice a week, the Gishurst being gradually increased in strength to a three-shilling box to 12 gallons of water, which is a very strong dose, and perhaps more powerful than is necessary. In this way a cure was effected, and the plants are now clean and free from the disease, and growing away well, considering the heat and absence of rain.

— FROM Mr. Culverwell, of Thorpe Perrow, Bedale, we have received a cut spray of *Tropæolum speciosum*, loaded with crimson-scarlet blossoms. This species he finds most useful in an ornamental point of view when allowed to over-run neighbouring shrubs, as for instance, the *Rhododendron*, and the soil that snits the one does for the other. Now, he says, is a good time for planting it, if strong plants for flowering next season are required; and, he adds, that most of the Scotch nurserymen keep it for sale in pots. It is better snited for bushes than walls, as in winter it leaves a blank on the latter; it may also be grown and staked like Peas where screens or blinds are desired. Many have expressed an opinion that it grows nowhere but in Scotland, which is a mistake; country makes no difference, provided it has a moist peaty soil to grow in. It grows and flowers well on walls at Barningham Park, the summer residence of Mark Millbank, Esq., in the north of Yorkshire.

— IN confirmation of Mr. McNab's remarks (see p. 193) on the Indian Garland flower (*Hedychium Gardnerianum*) Mr. Howell, of Heligan, Cornwall, informs us that he has a specimen of it which was planted out-of-doors six or eight years ago, and which is now bearing fifty heads of flower in different stages of growth, besides shoots not sufficiently advanced to indicate whether they will flower or not. The strongest shoots are about 6 feet 6 inches in length and are very stout at the base. It is planted in a small border at the west end of a plant stove where it receives no other protection than that which the house affords. It remained, he says, quite green all last winter, the old shoots only being cut out in spring when the young ones were a foot high. The flowers are beautifully scented. At the other end of

the house there is, it is stated, a noble specimen of the Coral tree (*Erythrina Cristo-galli*) on which there are some forty-five fine spikes of flower.

— MR. WARE has sent us some fine blooms of *Cyclobothra lutea* which he says is flowering freely in the open border at Tottenham, and which is likely to become a useful autumnal plant.

— WE have received examples of Blyde's patent flower or fruit-gathering scissors, which cut and retain the flower or branch at the same time. For cutting either flowers or fruit they will be found very handy; they are simple in construction and moderate in price.

— MR. VOICE, of Horley, sends us examples of his screws for tightening trellis or light fencing wires. They are cheap, and may be readily used by any ordinary workman; indeed, they constitute one of the simplest and most effective of raidisseurs.

— WE have received a copy of "The Rural Life of Shakespeare," by Mr. Roach Smith; a highly interesting pamphlet, containing, in a handy form, nearly all the passages from the poet's works, in which allusion is made to objects of natural history.

— WITH reference to our remarks on Chinese gardening (see p. 200), Mr. Hanbury writes to us as follows:—Chinese gardening is, he says, in a very primitive state, in spite of the poetical name given to the whole country, viz., "the flowery land." The Chinese are clever in dwarfing shrubs and fruit trees, and in making miniature lakes and artificial rock-work, but that is about all that can be said. I never met a Chinaman who, in our sense of the word, was either a fair botanist or a passable gardener.

— THE last number of the *Botanical Magazine* contains coloured figures of the following new or rare plants, viz.:—*Iris tectorum*, a native of Japan, having large blue or bluish-purple flowers. It flowered recently with Mr. Bull, who had it under the name of *I. tenuifolia*. *Bolbophyllum Dayanum*, a large flowered species from Moulmein, similar in habit to *B. cuprenum*. The flowers are greenish, blotched and spotted with reddish-brown, the segments being fringed with long hairs. *Cinnamodendron corticosum*, or Mountain Cinnamon of Jamaica, a West Indian tree having bright green leaves and axillary clusters of small bright orange-scarlet flowers; *Drosera Whittakerii*, a dense dwarf-growing plant from South Australia having large white solitary flowers on scapes about 2 inches in height; *Pentstemon humilis*, a dwarf plant 4 or 5 inches high bearing spikes of showy blue flowers. It is a native of the Rocky Mountains. *Brodiaea volubilis* a plant having a dense head of rosy flowers borne on a twining scape, which sometimes attains the enormous length of 12 feet. It is a native of California.

— FOR several years past the inhabitants of Soho Square have been vainly endeavouring to obtain power to throw open this square to the general public, but it was found to be impracticable. The fee simple of the property was supposed to be vested in the Duke of Portland, and all attempts to gain either an interview on the subject or the surrender of his lordship's rights having proved futile, a meeting of the inhabitants was convened and a committee formed. Mr. Albert Grant, to whom the public are indebted for Leicester Square, offered to lay out and develop the grounds at an estimated cost of £7,000, and to endow it with an annual income of £150 in the names of a committee to be appointed by the inhabitants. The square was originally known as King's Square, and in the centre stands a monument to Charles II. (in a very dilapidated condition), with four figures at the base, representing the rivers Thames, Severn, Tyne, and Humber. This will be removed at an early period, together with the present shabby rails and shrubs. The square will be surrounded by a sweep of wrought iron railings similar in design to those used in Leicester Square, the ground laid out in flower beds and walks, whilst statues of illustrious men, who, at some time or other, were residents in the district, will be placed at various points, amongst others Evelyn, who in 1690 lived there. At present there is a slight hitch in the acceptance of Mr. Grant's offer, owing to the opposition of a few of the oldest residents, who object on the ground that the contiguity of the square to the Seven Dials will cause it to be the resort of disorderly characters. The orderly conduct, however, of the visitors to Leicester Square, which of the two is nearer to the Dials, quite does away with this objection, and as the custody of the place will really be vested in the Metropolitan Board of Works the bye laws of that body are sufficiently stringent to cope with any danger. Mr. Grant's offer will be brought before the board immediately after the recess. Considering the very doubtful effect of the statues, &c., in Leicester Square we regret that it should be proposed to embellish Soho Square in the same way. In our climate, or in any climate, a building of some kind is the place for marble statues and busts; a garden is best, as a rule, reserved for trees and flowers and Grass. But, even if the square be unwisely and expensively "laid out," all lovers of gardens will be pleased to learn that there is a probability of another of the squares of London being rescued from its present condition of melancholy sliminess.

COMPARATIVE RATES OF GROWTH IN STEMS OF TREE-FERNS.*

By DR. MOORE, F.L.S., &c., Director Botanic Gardens, Glasnevin.

CONSIDERING that well authenticated data concerning the nature and rates of growth of tree-Ferns, would possess a certain amount of interest, I have arranged some notes made from time to time on this subject, on kinds which have come constantly under my observation. At the beginning of the period I purpose to review there were only very few of those beautiful plants introduced to Europe, and even yet, the number cultivated in collections is few, compared with those which are now known and described. The idea which is generally entertained concerning those plants is that they grow very slowly and that the stems of them, which are brought to this country from their native habitats, must have taken a great number of years to attain to the heights of 10 to 12 feet, which are about the largest sizes that are introduced. I have, however, been able to prove that the growths of several of the kinds are by no means so slow as they are supposed to be. We have grown at Glasnevin one species from a spore to a height of 10 feet in less than twenty years. It was, however, one of the most robust and quickest growing among the Australian and Polynesian species, the *Cyathea medullaris* (Swartz). When the late Dr. William Harvey visited some of the Polynesian Islands in 1855, he sent to Glasnevin a small packet of the spores of that Fern, or rather the variety of it, which differs from the normal New Zealand form in having more slender fronds, with their ultimate pinnales more divided, along with several minor differences, which have led authors to consider it a distinct species from the New Zealand plant. It is the *Cyathea Mertensiana* of Bongard, which the late Sir William Hooker, in one of his last works, "Synopsis Filicium," treats as a mere variety, differing slightly from the normal type.

A few plants were produced from the spores sent, one of which was grown on as rapidly as possible until 1872, when it had attained a stem 10 feet long in seventeen years. At this period of its growth, owing to some inexplicable cause, it turned sickly, and gradually dwindled away until it died during the present year. There is yet a fine example of the New Zealand form in the Glasnevin collection, which is historically interesting, from being one of the first batch of seedlings of this species raised by the late Messrs. Loddiges, of Hackney, about the year 1811. Another of the same lot perished in the conflagration which took place at the Crystal Palace a few years ago. I have no exact note of the time it came to Glasnevin, but suppose it must have been in 1815, when it was very small. It is now a noble-looking Fern, with a strong stem 11 feet high and fronds from 8 to 10 feet long. These examples afford us a tolerably correct idea of the sizes the stems of this species attain within thirty years. The next species I have reliable information on is that which is generally known in collections as *Alsophila excelsa* (R. Brown), but which I have reason to suspect is *Alsophila Cooperi* (Hooker). There are certainly two very distinct species in the Glasnevin collection, under the specific name *excelsa*, the common Australian kind, and that from Norfolk Island. The latter was grown from spores collected by the late Mr. John Veitch, taken from plants growing on Norfolk Island, and there are also plants in the same collection raised from spores taken from the fronds in the Kew herbarium, from which the late Sir William Hooker described his *Alsophila Cooperi*. I can see no difference between the latter and plants sent from Australia by my brother, Mr. C. Moore, of Sydney, as *A. excelsa*; but there is a great difference between them and the Norfolk Island plants brought by Veitch, which may be the true *A. excelsa* of Brown. The first plant of the Australian kind was sent in a Wardian case to Glasnevin, in 1850, when it had no woody stem, and the fronds only about a foot long, it has now a beautiful clean stem, nearly 12 feet in height under the fronds, which it has made within the last twenty-four years! I have also been able to observe the growth of *Dicksonia antarctica*, from a seedling upwards, to a rather large stem. The plant was obtained in 1810, when it was only about 8 inches high, including fronds; and now it has a strong thick stem fully 5 feet high from the surface of the tub in which it grows to where the head of fronds is. These instances, therefore, show that some of the Australian and Polynesian kinds of tree-Ferns make their stems quicker than has generally been supposed to be the case. There are, however, others of them which, so far as my experience concerning them extends, grow at a much slower rate. One healthy plant of *Alsophila australis* (R. Brown), at Glasnevin, was obtained when a seedling in 1850; and, although it has continued strong and healthy ever since, the rhizomatous stem is only now taking an upright direction. Another plant of the same species, which has been cultivated nearly as many years, has only begun to form an upright stem lately; and it, too, has continued healthy throughout. A further

instance is afforded of the slow progress many of those plants make during the earlier years of their growth, from a plant of *Cyathea dealbata*, which was obtained in 1855, and has grown vigorously ever since; yet the woody stem has only begun to form within the last eighteen months. These, and other similar examples, lead me to believe that many kinds of tree-Ferns make slow progress until their stems form and take an upright position; after which they grow much faster, until they attain a height of 12 or 14 feet, when the growth becomes slower and more consolidated. The observations I have had opportunities of making on South American tree-Ferns are confined to a few species. During the year 1858, the Hon. Judge O'Reilly, then residing in Jamaica, sent us from thence small plants of *Cyathea arborea* (Smith) and *Cyathea aculeata* (Willdenow), in a Wardian case, when they were without hardened stems. They soon began to grow vigorously, and the former has now a clean stem 13 feet high, the latter has one 5½ feet high, which they have made in sixteen years. Examples of the slow increase in height of Ferns after they attain a certain height, have been afforded by both Australian and South American kinds; among the latter, I may mention a fine plant of *Cyathea serra* (Willd.), which came to Glasnevin in 1862, from Lady Dorothy Neville's collection at Dangstein, when it had a stem nearly 15 feet high. It has continued in good health ever since, but it has hardly increased 3 feet in twelve years. Among the New Zealand kinds, fine plants of *Dicksonia squarrosa* (Swartz) and *Cyathea dealbata* (Swartz) were obtained in 1868, with stems 6 and 8 feet high. They have both continued in good health ever since, yet their stems have scarcely increased a foot in length in six years. To contrast with these, I may mention a plant of the beautiful *Cyathea princeps* (J. Smith), which has made a stem nearly 7 feet high within fourteen years. The foregoing observations have been made on plants growing in conservatories, to which the public are daily admitted, and, consequently, the atmosphere must necessarily be kept in a much drier state than is favourable to the healthy development of those plants. I have the experience of some fine examples of several of them which are growing in Dr. Hadson's splendid Fernery, near Dublin, at present; and also, those of Mr. Bewley's, where, in both cases, the atmosphere is kept close and moist, and with more shade, under which regime they make quicker growth in a given time than they do in the drier and more exposed conservatories at Glasnevin. The foregoing notes have not, however, been arranged for horticultural purposes, but simply, to afford some reliable data on the progress of the growth those plants really make, about which one hears so many mythical conjectures respecting the great age of their imported stems. I shall, therefore, not enter farther on the horticultural consideration of the question; but, before concluding, I may state my belief, that one-half, at least, of the many fine examples which have been imported during the last twenty years or so, have perished, owing to their being too freely exposed at first, and placed in situations unsuited for them. If they once get thoroughly checked, by being too dry at the roots or stems, they seldom recover, but gradually lose their fronds and die off. In summing up these brief observations, I have first to state, that some of the kinds of tree-Ferns grow with greater rapidity, and form their stems in a much shorter period than is generally supposed to be the case. Secondly: After they attain a certain height, the acrogenous buds are formed much closer together, the one above the other, than they are lower down on the stem, hence, their elongation is much slower. Thirdly: Some of the sorts which at first form short rhizomatous stems, before they take an upright position, require a considerable number of years to perfect the early part of their growth, but after the stem has been formed, and an upright position taken, the growth is much quicker and the elongation advances rather rapidly, compared with what it did while the stem remained in a rhizomatous state.

Considerable discussion followed the reading of this paper.

Dr. Hooker stated that at Kew they had not found their tree-Ferns to grow slower on attaining a height of 15 or 17 feet, as had been stated to be the case in the communication just read. There were some tree-Ferns at Kew nearly 30 feet high, which were growing as fast at that height as they did when only 10 or 12 feet. Dr. Balfour stated that at the Botanic Gardens, Edinburgh, they had resorted to the mulching of their tree-Fern stems with Moss, which had been found beneficial in preserving them from drought, &c.

A Large Flower Bed.—The great central plain of California for six months of the year is a scorched and dust-swept desert. In April it becomes one flower bed nearly 400 miles long and thirty wide, set under a range of snow mountains. A traveller writes of it:—"Go where I would—east, west, north, south—I was still surrounded by flowers which closed over my feet at every step as if I were wading in water."

* Read before the British Association at Belfast.

THE INDOOR GARDEN.

CYCAS REVOLUTA.

OUR illustration represents a fine specimen of this noble and distinct-looking Cyead, which is one of the most stately in the group to which it belongs, and eminently adapted for the decoration of conservatories or winter gardens. It is sufficiently vigorous in constitution to withstand the temperature of a moderately warm greenhouse during winter, and in summer it may be used in the flower garden, massed on the lawn along with *Aralias*, *Ficuses*, slender-growing *Palms*, and numberless other foliage plants of similar habit; while, when in a small state, plants of this species, together with its congener *C. circinalis*, are invaluable for room or balcony gardening. It is, however, as an indoor plant in which its true value consists; and, although one of the oldest of Cyeads, it is still one of the best in the whole group. The plant here represented is nearly 8 feet high; and, when such stately dimensions have been attained, it forms an effective object for grouping along with slender *Palms*, *Bamboos*, and other plants of a graceful character, in conservatories. It is readily propagated by means of the woody bulb-like masses which are freely borne on dwarf or stunted specimens. They are simply clusters of adventitious buds, that emit roots freely if placed in a pot of light rich compost. B.

HYACINTH CULTIVATION IN POTS AND GLASSES.

SELECT clean healthy-looking bulbs, not large (unless the sort produces a large bulb), but well-ripened heavy bulbs. It must be borne in mind that many varieties having small-sized bulbs very frequently give the best spikes of bloom, and must not be discarded. Procure them early, and do not select from those exposed in shop windows or in open baskets; this treatment sadly detracts from the bulb. The system adopted here is to keep them in bags, as imported, and we have found that the bloom is not deteriorated (although retarded), even if planted in December. The best compost is well-seasoned turfy loam, well broken, but not sifted, mixed with a large proportion of thoroughly decayed manure, and silver or river sand; but if this is not at hand, take any good garden soil, and a good proportion of well-decayed vegetable refuse or manure from an old hot-bed, to which add silver or road sand—in fact, anything to keep the soil porous. Avoid all soils that run together hard, for the more porous the soil, the better the bulbs succeed. If this compost is mixed together two months before it is used it will be all the better.

For Hyacinths in pots, any sized pots will do; we use for general purposes 6-inch or 32's. In potting, place a large crock or potsherd at the bottom for drainage, filling up the pot with compost. Clear the bulb from all offsets and loose parts, and press it into the soil, leaving the apex of the bulb above the surface. Have previously prepared a level plot of ground having a hard bottom of coal ashes, to prevent worms getting into the pots. Place them on this, and give them a good watering to settle the soil. After the surface has become moderately dry, cover the whole with fine coal ashes, old tan, sand, or any other like material, to the depth of 6 inches. Let them remain four or six weeks, so as to get the pots well filled with roots before the foliage starts into growth, as this is one of the most essential points. The time of potting should be regulated according

to the use required, but a succession of bloom may be had from Christmas to the end of April by commencing the second week in September, and continuing every fortnight to the end of December. After the pots are removed from the bed of ashes they should be cleaned from all impurities and gradually inured to light, and introduced into the forcing pit. Give them an abundance of water, and keep them as near the glass as possible. If not required for early purposes, they may be placed on shelves in a cool greenhouse, frame, or window sill, but protected from frost.

Hyacinths in water should be planted in Tye's Hyacinth glasses; fill the glasses previously with water (not from a spring, unless exposed to the air some hours previously), and place the bulb so that the base just touches the water. Then put them in a dark closet for three or four weeks, until the roots have grown some 3 or 4 inches, after which gradually inure them to light, and fill up the glasses with water. A few pieces of charcoal will help to keep the water pure, which it is not necessary to change unless it becomes offensive. Keep the leaves clean. The best position is in a cool room, as near the window as possible, but out of the reach of frost. October is the best month for placing Hyacinths in water. W. CUTBUSH & SONS.

Cycas revoluta.

Hydrangeas in Covent Garden.

—Doubtless some of our readers may have seen the beautiful little plants of *Hydrangea* now being brought into Covent Garden Market by the London market-growers. These plants are propagated from cuttings in the autumn and spring, and flowered in from twelve to fifteen months, bearing from one to four magnificent clusters of rosy blossoms. Some of the largest, or autumn-struck plants, vary from 18 inches to 2 feet across, and are literally one mass of bloom, and invaluable either for window-plants or conservatory decoration. I visited a small market garden at South Acton the other day, and saw a long span-roofed greenhouse quite full of this beautiful plant, while hundreds had already found their way into Covent Garden before my visit. In the turf-pits outside, 1,000 cuttings had been potted off ready for next year's supply; and this in one small establishment only—a fact quite sufficient to show the high estimation in which this plant is held around London. Old plants furnish quantities of fine cuttings, which strike freely in a moderate temperature, after which they are at once potted off in good fibrous loam, leaf-mould, and sand, and placed closely together in any empty space at command. The leading growth is pinched out at the second or third joint, so as to obtain strong bushy plants as dwarf as possible. As the pots become filled with roots, they are again potted on into 18's, and the larger ones into 32's, and in these they produce their flowers. During summer they are liberally supplied with water, a little manure-water being occasionally added to strengthen their growth. They are kept as near to the glass as possible while growing, and fully exposed to the sun, by which means the plants are kept dwarf and bushy. The aim of the market-grower is to get these plants into the market as early as possible, as a much better price is then obtained. Those now in the metropolitan market sell wholesale at from 24s. to 30s. per dozen, and are eagerly bought up at that price. The market-grower has but little difficulty in disposing of his flowering plants or cut flowers.—B.

Good Double Geraniums.—Have any means been successfully used of dwarfing or of reducing the too succulent and rampant growth of these plants, so as to make them more floriferous? This is much to be desired, as at present they grow too rank and leafy. A list of the best kinds and colours would oblige. I wonder at anyone recommending *Laxton's Aurora*, it is a semi-double useless kind, which I would not grow again. His *Jewel* and *E. J. Lowe* are first-rate.—W. H. B.

THE FRUIT GARDEN.

FRUITS IN LONDON MARKET GARDENS.

The Apple.

APPLES are naturally spreading-headed trees, well suited for standards, and, therefore, mostly grown in that way. They are planted in rows, varying from 15 to 20 feet apart, and they stand from 9 to 12 feet asunder in the row. For ordinary medium-sized trees, 15 feet by 9 feet are perhaps good distances, but I have seen hundreds of trees of Cox's Orange Pippin, a great favourite, in the form of dwarf bushes, on the French Paradise Stock, planted in rows only 6 feet apart each way. Apples are much more cultivated around London than any other sort of fruit tree, as they are more certain bearers than most other kinds of fruit, in consequence of the comparatively late period at which they flower, and there is always a ready sale for good Apples. Almost all our cultivated varieties of that fruit, including the newest as well as the oldest, are to be found in the market gardens, but certainly some sorts are more appreciated than others. The largest bearers, and such as produce fine handsome fruit, are usually the greatest favourites. The following is a list of sorts grown by Mr. Dancer, of Chiswick, and exhibited by him at a meeting of the Royal Horticultural Society, at South Kensington, where they were universally admired as the most superb samples of fruit from standards ever produced in the neighbourhood of London. Their names were—Fair Maid of Kent, Northern Greening, Small's Admirable, Cox's Pomona, Wellington, Blenheim Orange, Gloria Mundi, Brahmant Bellefleur, Minchall Crab, Stirling Castle, Braddick's Nonpareil, Hollandbury, Reinette du Canada, New Hawthornden, Beauty of Wilts, Kentish Fillbasket, Barchard's Seedling, Cox's Orange Pippin, Emperor, King of the Pippins, Scarlet Nonpareil, Ribston Pippin, Mère de Menage, Northern Spy, Cellini, Incomparable, Ingestrie, Old Golden Pippin. To these may be added Lord Suffield, a great favourite and heavy cropper, Salopian, Julian, Norfolk Pippin, Court of Wick, Autumn Pearmain, Oslin, Ord's Apple, Bess Pool, Baxter's Pearmain, Devonshire Quarendon, Early Nonpareil, Kerry Pippin, Syke House Russet, Wormsley Pippin, Carlisle Codlin, Yorkshire Greening, Tower of Glammis, Nonesuch, Nelson Codlin, Rymer, Keswick Codlin, Golden Noble, and many others. Barchard's Seedling is a beautiful medium-sized Apple, richly coloured, and an immense bearer. Although Mr. Dancer has several large trees of it, it is comparatively new to cultivators. He received a first-class certificate for it at South Kensington last year. Unless Apples, like other fruits, are of first-rate quality, they fetch comparatively low prices; hence, it is, that Apples are so largely imported from the Continent, and from the United States of America. The American Newtown Pippins arrive in this country in such good condition, and are of such fine quality, that, in their season, they stand at the head of all fruits in the market. During the scarce season, nice eatable Newtown Pippin Apples realise from 3d. to 6d. a piece. Dealers state that it is cheaper and better for retailers to pay 70s. a bushel for such American Apples, as have been re-picked by the wholesale men at Liverpool and Glasgow, than it would be to pay 40s. for them just as they arrive. The Apples are packed firmly in barrels, no kind of packing being used, and they travel and keep satisfactorily treated in that way.

The Pear.

Pears are chiefly grown on the old-fashioned standard run-wild system, no pruning being given but what is done with the saw; and, in a good season, it is wonderful how heavily the trees are laden with fruit. These standards have been "worked" on the Pear stock, which forms a clean stem, the branches usually springing from near the union of the stock with the scion. There are dwarf Pear trees, too, and many that succeed better on the Quince than on the Pear. Market gardeners generally are not, however, very particular about their stocks, for they get the bulk of their trees at the nurseries, and what they graft themselves is usually done on whatever stock they have at hand, be it seedling, sneker, or layer of Pear or Quince. They practise grafting more on old and worn-out trees than on young stocks, and for this purpose

they head back the trees in winter or early in spring either at pruning or digging time; the scions, after being selected, are "heeled in" until March, when they are put on the trees. Grafting more than one kind of Pear on a tree is said to be a preventive of fruit cracking during the swelling period. This is the experience of Mr. Mills, of Chiswick; and, on paying a visit to his grounds early in September last year, I was much struck with his remarkably fine Pear crop. Not only was it an unusually heavy one, but the size and symmetry of the fruits exceeded anything I had previously witnessed on standards. On directing attention to this fact, Mr. Mills admitted that it was universally acknowledged that the very piece of ground on which these trees were growing was the finest natural Pear-tree soil in the district. It was a somewhat light yet deep, substantial, hazely loam. In reference to cracking, he informed me that many years ago he found that, although the trees were in a thriving and healthy condition, and annually set good crops of fruit, yet, at gathering time scarcely a half sieveful of good marketable fruit could be obtained from them, the fruits being invariably all cracked. This induced him to try the effect of grafting more than one sort on each tree, and the result proved most satisfactory; for, not only did the grafted portions produce excellent fruit, but the original kinds no longer cracked; on the contrary, they produced fruit of exceedingly fine quality, well-formed and symmetrical. Finding grafting in this way successful in a few cases, he extended the practice throughout his orchards; therefore, where one kind of Pear grew alone on a tree, now there are at least three sorts, each apparently being of material benefit to the other. I noticed a number of trees, formerly Beurré Diel only, that consisted of that sort as a centre-piece surrounded by Beurré Bosc and Louise Bonne, the branches of all three sorts bending under a heavy burden of fine Pears. Bishop's Thumb was the only sort that I saw doing well by itself, and its fruits were so large as to be quite unlike the usual type. Mr. Mills also informed me that the Duck's Egg does well alone, and is a valuable early market Pear. Of William's Bon Chrétien no fewer than 100 bushels were sent to market from one garden alone in one day. In addition to a plurality of kinds, it is found that running a longitudinal cut down the bark of the stems every second year is of material benefit to Pear trees, inasmuch as it prevents the stems becoming hide-bound, and producing sudden swollen protuberances near the union of stock and scion such as are often observed; besides, it maintains a healthier connection between the branches and the roots, than would be the case if the stems were bark-bound. Mr. Pitman, the fruit tree foreman at Osborn's nurseries, also recommends this practice. In the case of fruit tree stocks, particularly those for standards, Mr. Pitman, before grafting, and even a year or two afterwards, permits some little twigs to grow out of the stock or trunk, but he pinches them always well back; this he maintains prevents hide-binding, and helps to strengthen and increase the size of the stems. The necessity of a change of crop, in regard even to fruit trees, was plainly evident in Mr. Mills's grounds. In a portion of them old Pear trees had been grown for years; these were removed and replaced by young ones, but the latter have made but indifferent progress, while, had Apple or Plum trees been substituted for the young Pears, the result would probably have been more satisfactory, as both of these thrive remarkably well in company with Pears. Last September, Mr. Mills, having occasion to leave home for some time, had all his Pears harvested before his departure, marketing such as were ripe and ripening, and storing the rest. The result was, that he had some of the very finest-flavoured fruit ever tasted. Louise Bonne was splendid, and Beurré Diel he never had so fine, giving him a succession of ripening fruit from October till February. He, however, regards Beurré Bosc as the king of market Pears, on account of its prolific bearing-habit and handsomely-formed and large-sized fruits, of fine quality. The distance apart of large standard trees is, as I have stated, very variable, but from 12 feet to 20 feet may be regarded as the average for rows, and from 12 feet to 16 feet asunder in the row. In fact, in some cases, the trees are growing so thickly together, that their branches partly intertwine, whilst, in others, the distance is sufficient to give ample room to the trees, and space and exposure enough to both bushes and vegetables growing

between them. The trees are not all tall standards, however, for some are as dwarf and symmetrical as one could wish to see. Mr. Dancer prefers naturally grown bushes to rigid French pyramids, as the former bear more fruit and resist wind better than pyramids. Some kinds of Pear trees have naturally a pyramidal habit, which, as a matter of course, is encouraged. Mr. Dancer's bush Pears are in rows, about 9 feet apart and 8 feet asunder in the row, and he has some even closer than that. Of wall Pear trees, or, in fact, of fruit trees of any kind grown against walls, there are but few in market gardens, and such as are grown in that way are often much neglected. I have, however, frequently met with trees, chiefly Pears, planted against a north or east wall, and having their branches trained fan-shaped down the other side. This enables south borders to be cropped without interfering with the roots of the trees, and also prevents the trees from starting into growth so soon as they otherwise would do, and hence diminishes the chances of their being injured by spring frosts. In order to indicate the kinds of Pears grown in market gardens, I append the names of the sorts exhibited at South Kensington last autumn from Mr. Dancer's gardens, and which, as regards excellence and size, contrasted favourably with those sent from France and the Channel Islands:—Beurré de Capiaumont, Althorp Crassane, Bishop's Thumb, Seckel, Napoleon, Beurré Léon le Clerc, Conseiller de la Cour, Dr. Nelis, Winter Nelis, Marie Louise Nouvelle, Colmar d'Arenberg, Gratioli, Madame Treyve, Louise Bonne, Marie Louise, Belle Julien, Beurré d'Arenberg, Fondante d'Antonne, Beurré Hardy, Durandau, Bergamotte Cadette, Baronne de Mello, Huyshe's Victoria, Urbaniste, Doyenné du Comice (fine), Bergamotte d'Esperen, Bezi Mai, Catillae, Marie Louise d'Uccle, Beurré Clairgeau, Beurré Bachelier, Léon de Clerc (Van Mons), Belle et Bonne, General Todtleben, Calabasse Grosse, and Beurré Bose. In addition to these there are also grown Glou Morceau, Beurré Rance, Thompson's, Windsor, Doyenné d'Été, Ne Plus Meuris, Knight's Monarch, Soldat Esperen, Broom Park, Comte de Lamy, and many others. A great proportion of the best dessert Pears seen in the English markets are imported from France and the Channel Islands. Indeed, California and many parts of Eastern America are likely to play an important part as regards furnishing Pears to the English markets; but the distance and length of time that elapses from the period when the fruit is packed till it is unpacked in England sometimes tells badly in regard to Pears.

Plums.

These are extensively grown in the form of standards, and but a small proportion is cultivated against walls. The standards are chiefly grafted or budded on the Muscle stock, or Plum tree suckers are preserved and lined in to be used as stocks. It is difficult to give exactly the distance between the trees as they are planted so variously in different gardens. Rows 12 feet apart, and the same distance from tree to tree in the row, or 15 feet by 15 feet, may, however, be considered to be the most general distances. As far as I have been able to observe, the greater the distance between the rows the heavier is the crop of fruit; besides, wide planting is better for vegetables growing underneath the trees than close planting. As Plum-tree roots keep so close to the surface of the soil I consider the market gardener's method of deep digging annually between the trees a commendable practice, as he thereby prevents over luxuriance by repeated root-pruning, which is never so severe as to be injurious; besides, were he to leave the ground for one year undug it would be dangerous to dig it next season on account of the injury that would thereby be done to the trees, and he would also lose his under crops of vegetables which are always useful, in so far as they render the loss of the fruit crop less to be regretted. The digging, however, together with the annual heavy manurings renders the trees very productive, so much so that I have seen the young Plums thinned a little three times before a crop was permitted to ripen, and even that had to be picked gradually, taking the ripest first, or else one half of the fruit left would never have ripened. The trees, too, required supports in the way of forked props put under their branches. The kinds grown consist of those usually cultivated in ordinary gardens, especially Damsons, Belle de Septembre, Coe's Golden Drop, Victoria, Jefferson,

Mirabelle, Gages, Blue Imperatrice, Royal Hâtive, Kirke's, Washington, and others.

Cherries.

The Cherry orchards of the south of England are celebrated for their beauty when in flower, and the richness, quality, and quantity of their fruit when ripe. Cherry trees are principally grown in Grass orchards, particularly in Kent, and are therefore rather beyond the bounds of what may be termed metropolitan market gardens. In these, however, Cherries often find a place; indeed, I never yet saw Kentish Grass orchards bear such fine fruits, or so plentifully, as I have seen some young trees do in Mr. F. Dancer's gardens at Chiswick. These trees are in the form of dense, but open-hearted, bush standards, grafted near the ground on the Mahaleb stock. This stock, however, is only available for dwarfish-growing kinds, such as the Kentish and May Duke. Cherry seedlings make the best stocks for strong growers, like the Bigarreau. Dwarf trees are usually kept trim by means of the pruning knife, although few trees dislike cutting so much as the Cherry. Tall standards are allowed to grow at random; indeed, they make so little young wood that pruning, beyond removing dead wood, is seldom necessary. The kinds chiefly grown are the Kentish, Black Heart, Knight's Early Black, May Duke, Late Duke, Elton, and Morello.

Raspberries.

Raspberries are a profitable and accommodating crop. Raspberry culture in market gardens may seem to some to be carried on with comparative carelessness, compared with the staking and arching methods practised in private gardens. The Red Antwerp is almost the only variety grown. The stools are planted in rows 3, 4, or 5 feet apart, and from 20 inches to 2½ feet asunder in the row, but 3 by 2 feet may be regarded as the usual distances. At pruning time—say November—the canes are thinned out to six or thereabouts, if there are so many, and these are cut over about 2½ or 3 feet from the ground. In early spring these are loosely tied together with a piece of rope yarn, no stakes being used. The Raspberry plantation may either be in an open quarter, or rows of Raspberries may be planted between fruit trees, and intercropped with ordinary quick growing vegetables. The plants get no further care, beyond the replacing of a loose tie, till gathering time; nevertheless, thus treated, I have seen them bear immense crops; I must confess, however, that I have seen larger and finer berries grown in private gardens than I ever did in a market garden. F.

SMALL VERSUS LARGE POTS FOR PINES.

ONE of the prevailing evils of the age, as regards Pine-growing, is large pots. 12, 14, and 16-inch pots are the sizes generally used to produce fruit 3, 4, and 5 pounds in weight. An impression seems to prevail that plants grow in proportion to the sizes of their pots, and that the largest plants will bear the best fruit, which is not by any means the case. My experience of large pots is, that they require much more room than smaller-sized ones. The space required for two plants in 14 or 16-inch pots would accommodate three in 10-inch ones; plants in 14 and 16-inch pots to have sufficient space require at least 3 feet between each plant in the row, and supposing a Pine-bed to be 100 feet long and 3 feet wide (which are the dimensions of some here), at this rate there would only be thirty-three plants in the row, or sixty-six in the bed. Plants in 10-inch pots have ample room, plunged 2 feet apart, which allows of fifty plants in the row and one hundred in the bed. This gives thirty-four more plants when in the small pots than in the large ones, in the same space, which means thirty-four more fruit. As to weight, allow the average to be 4 pounds; out of the sixty-six in large pots there are 264 pounds of fruit, while those in the small pots yield 136 pounds more, or 400 pounds of fruit altogether—besides other advantages, the positive gain in this way, is absolutely unquestionable. These calculations are not vague speculations; I have seen them verified repeatedly. There are, however, other unprofitable disadvantages connected with large pots. I consider plants in the larger-sized pots generally take six, and often twelve, months longer to come into fruit than those in the small ones. The reason of this difference is easily explained. It is next to, if not quite, impossible to get a Pine into fruit if the pot is not entirely filled with roots. Few, if any, of even the strongest-growing Pines will fill a 16-inch pot sufficiently full of roots in one season to ensure fruit; and, if fruit is not got from

the first growth, farewell to any definite period when it can again be had. Plants in small pots make plenty of roots in four months; while those in the larger ones, at the end of that time, are few and far between. I am convinced that a well-packed potful of healthy roots does ensure and produce fruit in a far more perfect manner than any quantity of leaves. As to the ease of the plants in the large pots, taking so much longer to come into fruit than the small ones, three crops may be secured from the latter while only two can be depended on in the same time from the former. Generally, there is no variety of Pine so uncertain of fruiting as the Queen, and there is none that will fruit surer or more satisfactorily in a small pot than that variety. I believe that the whole of its freaks in fruiting are due to the large pot in which it rambles about. I have frequently observed that the plants most liable to show any tendency to ill health were those in the largest pots. A 16-inch potful of soil, with not many roots therein to utilise the moisture, takes a long time to become dry when thoroughly soaked with water, a circumstance which is not always taken into proper consideration. Pines, like other small plants put into large pots, are lost for a considerable time, sometimes altogether. Even youthful vigour takes a long while to overcome and thwart the many impediments which it has to encounter in this way, I have seen young Pines potted out of 6-inch sucker pots into 14-inch ones, others shifted from 6-inch ones into 10-inch ones, and from these into 16-inch pots, thereby giving much unnecessary trouble and labour.

J. Muir.

THE SUSSEX FIG ORCHARDS.

AUTUMN visitors to Worthing and its vicinity may have noticed the abundance of green Figs which are offered for sale there during the season, but it is not generally known that this fruit is cultivated not only to an extent but also in a manner that is peculiar to that part of Sussex. In other parts of England we find single Fig trees trained along the wall, but here there are whole orchards full of these trees grown as standards, some of large size and patriarchal age, and so thickly covered with broad indented leaves that they irresistibly bring to mind the scriptural figure, whereby a period of peace and prosperity is indicated by a man "sitting under his own Fig tree." Notwithstanding the neighbourhood of the bare chalky downs, there is immediately above Worthing a belt of very fertile country, with a light clayey soil. Probably there is not in all England a more garden-like district than this; the lanes and hedgerows are bright with wild Honeysuckle and Clematis, and wood Anemones and wild Strawberries rustle in copes. Gardens in general abound in this district, but the special object of culture is the Fig. In one orchard at Tarring there are no less than 120 large standard Fig trees, which sometimes in a good season produce upwards of 2,000 dozen of Figs. A goodly sight it is to see the luscious blue-black fruit hanging from the trees, beneath whose overarched and interlacing boughs one walks as in a bower. The crops vary a good deal, both in quantity and quality, according to the season. This year it is a good crop. The heat and dryness of the "comet season" have been propitious to the Figs; and in another week or so the inhabitants of this region will be busily occupied in gathering the fruit, and packing a large portion of it for transit to Covent Garden and Brighton Markets. The trees at Tarring are very old, having been planted more than 100 years, but the old stocks in a garden occupying the same site, from which these were taken, are gifted by tradition with a greater age and more illustrious origin. They are said to have been placed there by no less a person than Thomas-a-Becket. That famous ecclesiastic—as the story goes—on his return from Italy brought with him the Fig which he was the first to plant on British soil. Whether the tradition be true or not, it seems certain at least that the martyr Archbishop did sometimes reside at Tarring. The ruins of a house which is said to have been his palace are still shown, and the Vicarage of Tarring remains to this day in the patronage of the see at Canterbury. The neighbouring village of Sompington claims a still higher antiquity for its Figs. Going back to the time when the kingdom of England was an appanage of a Norman dukedom, it relates how the Abbot of Fécamp, on the opposite coast of Normandy, who was accustomed to honour this island with an occasional residence in it, purchased a manor at Sompington and introduced the Fig. As a credential of the truth of this story it points to the name which the place still bears Sompington-Abbots. But there is a another and more modern visitor from foreign parts who makes an autumn trip, each year, to the Sussex Fig orchards, and the report of whose annual advent rests not on uncertain tradition, but on the concurrent and indignant testimony of the Fig growers. This is none other than the Italian Baccanale or "Fig-eater"—not one of the native species to which the title of "Fig-bird" is sometimes given, but the genuine "Fig-eater" of the Roman Campagna. Unknown to any other part

of England, this knowing little "gourmet" has discovered that his favourite fruit has been transplanted here, and shows his appreciation of the success with which it is cultivated by travelling northwards every year at the beginning of September, and paying an uninvited and unwelcome visit to the Sussex Fig orchards. At the close of the Fig season, and before the first frost has given notice of the approach of winter, he spreads his wings and returns to the shores of the Mediterranean. So writes a correspondent of the *Morning Post*, concerning the Sussex Fig orchards, which are most interesting to the English fruit-grower, as showing that the Fig can be grown with perfect success as an orchard tree in England. We have recently visited some of the most extensive of the Sussex orchards, and found that whatever merits they have, is in no way owing to cultivation or pruning. We believe that with the introduction of early and superior kinds of Figs and improved culture, we could have Fig orchards in England as good as any in existence. Apart from the fruit, which is destined, like the Tomato, to become much more popular in England than it is, the Fig is an exceedingly beautiful tree when grown as a standard. We have seen some in the south of France this year, 60 feet in spread of branches, and though trees in England would probably never attain that size, they would grow large enough to prove very ornamental objects.—Ed.]

A Simple Method of Cleaning Melon Seed.—Some little ingenuity is required to free the seeds of Cucumbers and Melons from the slimy mucilage in which they are imbedded in the ripe fruit. Gardeners generally save these seeds from some particularly prolific or richly-flavoured variety in which they have full confidence, and each adopts a system of his own in cleaning the seed. I have tried washing in water, rubbing in dry sand, and several other methods, but, as regards simplicity, the following is best:—Place the seeds and pulp, just as extracted from the fruit, in a piece of fine netting or tiffany and squeeze the whole so as to get rid of superfluous moisture, and then empty the mass of pulp and seeds into a coarse towel and rub them dry. This can be done in five minutes and every seed will be as clean and as bright "as a new pin," and their is no danger of mildew or Fungus attacking seeds thus cleansed if they are stored in a dry place.—F. W. B.

The Best Currants.—The old Red Datch and White Datch are good, reliable sorts, and we would not advise anyone who has them growing in his garden to throw them out. Larger Currants, however, may be picked more readily; they make a finer show on the table, and they last longer on the bushes without shrivelling. The two sorts that we place above all others, therefore, are the White Grape and Versailles or Cherry. Mixed together, they make a beautiful table dish. The only drawback on the White Grape is the slow and straggling growth of the bush; but this objection is obviated by giving them clean and mellow culture, applying manure occasionally, and keeping them sufficiently pruned. It will not do to neglect them, and to allow them to become enveloped in Grass and weeds, the usual fate of Currant bushes with careless managers. The Cherry, on the other hand, is a strong grower, and does not absolutely need such generous treatment, but it is better to cultivate it well, and prune the bushes as they require it. Our own bushes of the Cherry, which have stood in the garden fifteen years, are three times as large as those of the White Grape planted at the same time, and they always bear profusely. When allowed to hang long, and become fully mature, they lose their objectionable acidity, and are a rich and agreeable berry. The Versailles is so nearly like the Cherry, that if the planter has one, he need not take the trouble to procure the other—although the bunches of the Versailles have the advantage of being rather the longer. The Victoria and Prince Albert are good very late varieties—the former red, the latter pale red—a few of which may be planted for a succession. All that is absolutely needed in the pruning which we have alluded to, is to cut out the old and enfeebled wood, to give the younger shoots, evenly distributed through the bush, a better chance to grow. This will make large bunches and berries.—*Cultivator*.

Trebbiano as a Late Grape.—I often wonder this fine old variety is not more generally grown, as its quality is really excellent when thoroughly finished off with a little fire heat and plenty of sun and air. Here it makes a nice addition to the winter's dessert, and forms a good companion to Barbarossa, the latter being another fine late Grape which requires similar treatment.—B. J., *Farnham*.

Fruit in Yorkshire.—Apricots have been so plentiful that at Thirsk, Northallerton, and Richmond, they could be bought at from 6d. to 8d. per score. Some of the wholesale buyers offered only 2s. 6d. per score for them. Victoria Plums realised a good price, viz., 6d. per pound; Orleans Plums fetched 4d. per pound. The difference between weight and measure is that 3 pounds of Plums would be equal to 2 quarts. Apples are selling at from 2d. to 4d. per pound; Jargonelle Pears from 3d. to 6d. per pound, according to size and quality; common Pears are 2d. per pound.—T.

THE FLOWER GARDEN.

POT CULTURE OF THE IVY HAREBELL.

(*CAMPANULA HEDERACEA*.)

THE best way to get this graceful British plant into cultivation is to secure a plant from its native habitat; but, failing this, it may be readily obtained from seed, which is to be found on plants of it in September. It must be particularly noted, as regards its cultivation, that it is a trailing herb, with shoots 18 inches or more in length, and that the prettiest way is to let it hang over a pot all round, a 7-inch or 12-sized one suiting it best. It grows well during the early part of the summer, if kept in a nice moist condition, never dry, as it is in reality a bog plant. Do not, however, try to grow it in a pot plunged in water, for, under such treatment, it will soon die; and it is singular that it should do so, seeing that it only roots half an inch deep or so at the most. After blooming it gradually dies back, when seed may easily be saved from the old stems. During winter it will be dwarf and sickly looking; but this may be disregarded, and, as soon as it shows signs of moving in December or January (if kept in a greenhouse), it should be re-planted in the pot, filling up with nice open soil, and plenty of drainage to within about an inch of the rim; then get a piece of the old plant, which will be found like a net, half an inch thick of fibre and underground runners, and after opening it out a little, lay it on the mould in the middle of the pot, and cover it over with small bits of turfy mould to the thickness of half an inch; water it and keep it moist, and it will very soon run all over the pot, coming up at the edges, and finally hanging down all round, and blooming beautifully. Though a hardy plant, few gardens can supply the conditions of a turfy moist corner for it, and it is as well to know that it does first-rate in a greenhouse. It is a thoroughly good plant for indoor culture for either amateur or connoisseur.

A. DAWSON.

THE PLANTING OF GARDEN VASES.

VASES for flowers are made of various shapes, and the shape should determine the way in which the vase should be filled. There is the flat shallow vase with broad brim, inviting you to hang a fringe over the edge, and a little garden of plants gently swelling over its surface; then there is the tall deep vase, which should be planted fountain-like, plants tall and spreading. Then there are vases intermediate between a cup and a bottle, tall, large in the centre, and contracted at the neck, with perpendicular-looking handles or ears; these should be planted with something tall in the middle, and with dwarf trailing plants frothing over the shoulders; again, there are vases of all intermediate shapes, some flattish, with swelled bodies and rather contracted necks, some neither the one nor the other, but capacious, with exaggerated freedom of handle; some in the form of Tulips and Water-Lilies, some ornamented with goats' heads and

griffins, some encircled with human heads, with ample flowing beards that ultimately get obscured when the tresses of Minnie Warren or the sprays of *L'Elegante* fall over them. As a rule, flat vases should be planted with dwarf plants, giving the vase at a distance a flat rounded outline. Tall vases should be planted with tall things in the centre, modifying the manner of planting with the intermediate shapes. A tall cup-like vase would look poor with a short flat bouquet of flowers growing on the top of it; but with tall fountain-like plants in the middle, with the rim gracefully covered with some trailing plant, it will prove a pleasure to look upon. A flat shallow vase planted with tall plants would look even worse, or propped up to a pyramid like the top of a Wheat-stack, as is often done. We have tried various modes of planting vases; we have had immense bouquets of one sort of plant, which were showy enough from a distance, but vulgar; planted in rings of colour, ribbon fashion, is perhaps worse; in almost every instance, except when the vase is very small, and a single plant sufficient, it is much the best to use a mixture of plants.

Materials for Filling Vases.

Ours, like our flower-beds, are filled twice a year—in summer, at the bedding-out time, with summer-flowering plants; and again, in the autumn, with hardy plants. The summer plants are all of the same character as the bedding plants, of which *Geraniums* form the

staple for the vases; but we find that, as a rule, the cuttings of the autumn are not of much use; large plants in small pots are the best, the top fills out when for the time the root occupies but a small space. Lifted plants from the beds in the autumn, of whatever sort, can always be put into small pots and kept so throughout the winter; this applies to *Mesembryanthemums*, *Ivy-leaf Geraniums*, *Abutilons*, *Gazanias*, *Cineraria maritima*, *Centaurea gymnocarpa*, *Tropaeolum Minnie Warren*, and others, as well as to the general run of *Geraniums*. A special eye must be had to plants for vases where

The Ivy Harebell (*Campanula hederacea*).

there are many to fill, else there will be disappointment when the time of filling comes. Much can be got ready in spring, and grown into the desired size, such as common *Tropaeolums*, *Lobelias*, *Petunnias* from seed, *Calceolarias*, *Verbenas*, and cut-back *Fuchsias*. There is quite a wealth of plants suitable for vases when prepared for the purpose; but the chief point is the tasteful planting of the vase: these, like flower-pots, should be provided with a hole in the bottom to carry off superfluous water, although it is seldom they get over-watered. A small pot may be put over the hole, mouth downwards, or a few large crocks, just to prevent the hole from becoming stopped up. Many crocks are objectionable, except when the vase is very deep and bottle-shaped.

Soil for Vases and Planting.

The soil used should be a mixture of fresh fibrous loam and rotten dung, the richest which can be had, the soil to be put into the vase as the work of planting proceeds. It is convenient for the work and for comparison to collect all the moveable vases to one place where the heap of soil is, and the plants at hand for selection as wanted; the work of filling then goes on more expeditiously. In planting, begin at the rim with the plants which are to hang over the edge. *Pelargonium Willsii* roseum, *Ivy-leaf L'Elegante*, *Duke of Edinburgh*, *Minnie Warren Tropaeolum*, and *Lobelia*, make a fine mixture for a marginal row to hang down; the old pink *Ivy-leaf Geranium*, *Mangle's*

Variegated, spreading plants of *Gazania* and *Abutilon vexillarium marmoratum*, with *Cineraria maritima* and *Lobelia*, also make rim plants; the next series inwards may consist of *Coleus*, *Centaureas*, *Calecolarias*, *Fuchsias*, and various *Geraniums*, choosing the plants as to size until the vase is finished; but we do not care for finishing a vase with one conspicuous staring plant in the centre, as is sometimes done. It is often necessary in planting vases with a bulging shoulder to run two or more thin wires round on which to tie the hanging plants in order to prevent them from being chafed to pieces by the wind; they also look much better regulated and tied down; some done in that way here are much the most effective, for, although tied, they still appear to hang. For the centres of tall vases *Acacia lophantha* is very useful with a piece of bare stem, to which can be tied the long sprays of *Abutilon vexillarium marmoratum*; the variegated Japanese Maize also suits well for this purpose; pyramidal-shaped *Fuchsias*, the narrow-leaved *Dracaenas*, *Humea elegans*; also for such vases I use plants of the semi-trailing *Geranium Orange Nosegay*, *Centaurea gymnocarpa*, *Salvia patens*, with a few plants of *Petunia* to fill up the bottom and hang gracefully over. Few plants are better adapted for vases than *Petunias*, which flower more profusely when pinched for root-room; but water must be supplied to them liberally—indeed, the question of water must always be particularly attended to, and with a liberal hand. Sometimes it will be necessary to soak the vases thoroughly twice a day; for, if once allowed to get too dry, their beauty is marred for the season. After midsummer weak liquid manure should be given every time they are watered; for, if allowed to get seedy and starved, instead of an ornament, they become a decided eyesore.

Winter Vases.

Vases for winter may be filled in various ways: first of all, dwarf shrubs may be used entirely; one shapely *Rhododendron* will fill a vase at once, or a mixture of small things may be used. The pretty *Erica herbacea* makes a nice winter edging, and the various *Vincas* and *Ivies* are suitable for hanging over; we used *Aucubas* and *Retinosporas* largely last winter. *Retinospora pisifera aurea*, *Euonymus radicans variegata*, *Erica herbacea*, *Iberis sempervirens*, and *I. tenoreana*, are stocky little plants, which associate well together in filling vases. *Festuca glauca* in thick tufts also harmonises well with these, but it loses its blue colour in winter. None of these seem to suffer much when the soil is allowed to be dry; they were never watered; and if the soil is raised in the middle and made hard on the surface, much of the rain runs off. The chief feature last winter, however, in the way of vase-filling was in the use of hardy succulents for low flat vases, such as *Sedum glaucum* and *lucidum*, *Sempervivum californicum*, *montanum*, and the common House Leek; *Saxifragas*; also variegated *Thyme*, *Pyrethrum Golden Feather*, &c. A very pretty and tasteful effect may be made with such things in large vases if they happen to be under the eye, the soil raised and rounded over, and each vase planted with a different design like a miniature flower-bed. The *Golden Feather* and *Golden Thyme* associate well with the succulents, and the drier the soil the more successful will be the result—*Golden Feather* being the least satisfactory. In planting vases at all times we never make any allowance for growth, but plant thickly and make them look full at once; the plants then support each other, they have plenty of room to extend themselves outwards, and the effect improves as they get interlaced. If possible, it is always better to group the vases in some shady sheltered place for a few weeks after filling in summer, before being placed in exposed positions on terraces in the blaze of the sun; this is, however, not so necessary in the case of large vases with a large body of soil in them as with smaller ones.—*The Gardener*.

***Saxifraga floruenta*.**—I have made several attempts to grow this interesting species, which, I believe, has hitherto almost baffled the attempts of English cultivators. In 1872, I collected a considerable number of plants from an Alpine ravine above St. Martin Lantosca, nearly the whole of which, including those I distributed to other gardens, were lost, and, I believe the plant is not capable of pot-culture. With a further supply obtained last autumn, I have been more successful, and have now about a dozen plants in luxuriant growth. In its native habitats, the rosettes almost invariably grow in a vertical or partly inverted position, generally under projecting ledges of rock with a northern aspect, and, I believe, that success in its cultivation can only be attained by imitating as closely as possible these natural conditions. M. Boissier, I understand, grows it in the interstices of a brick wall, and following his example, I find that the plant is quite amenable to cultivation. Of seven plants I wedged tightly under the coping stone of a brick tank, six have become nicely established, and are increasing rapidly in size. This position seems just to supply the native conditions of the

plants, viz., moderate moisture, and firm root-hold, thorough drainage, vertical shelter, and northern exposure. I have also several plants in good health, wedged tightly into the crevices of the northern side of a steep bit of rock-work. The figure in the *Botanical Magazine* for June, from a specimen I found in flower last September, near the summit of the Col du Finestrelle, in the Maritime Alps, faithfully represents this beautiful species, which is a Dodo amongst *Saxifragas*. It has no near ally, and is only known to exist within a limited district of a few square miles, in the highest parts of the range of the Maritime Alps, west of the Col du Tenda. Judging from the association of species in the central mountains of Corsica, I think it not at all improbable, that it may also be discovered in the Monte Rotundo district, near Corte.—GEORGE MAW, *Bentham Hall, Grosvenor*.

Hardy August and September Blooming Plants.—I find that my garden is pretty gay with flowers of hardy herbaceous plants during the spring and early summer months; but, in August and September, I have but few plants in bloom, and should therefore be obliged by your giving me the names of some of the best hardy plants that flower in these months.—SIMON. [Among the finest of autumn-blooming plants are the red-flowered *Anemone japonica*, and its beautiful white variety known as *Honorine Jobert*; the genus *Aster*, also, affords some highly attractive autumnal blooming plants, among which *trabinellus*, *pyrenaeus*, *Drummondii*, *Shortii*, *Novi-Belgii*, *Novae Angliae*, *levis*, and its varieties, are the best. In many places the *Arundo conspicua* and *Pampas Grass* are also highly attractive in September, particularly the latter. The *Snape-dragon*, too (*Antirrhinum majus*), will be found worthy of attention, as will also many sorts of *Fuchsias*, especially *F. gracilis*, which, for general purposes of decoration, is, we think, the best, being both very hardy and floriferous; *Coreopsis lanceolata* is usually a mass of bloom late in summer, as are also such plants as *Phygelis capensis*, *Pyrethrum serotinum*, a tall late flowering species, *Eupatorium purpureum*, *Helianthus autumnale*, *Helianthus multiflorus* fl. pl., a free-flowering kind, the blooms of which are as large and as conspicuous, in most cases, as those of a yellow *Dahlia*, for which it forms a capital substitute. Several of the *Stoncroops* (*Sedums*) bloom freely in August and September, and rank amongst the most attractive of hardy herbaceous or Alpine plants. We especially allude to the now well-known *Sedum spectabile*, which produces masses of rose-coloured flowers in abundance, as do also two distinct dwarf species known as *Sieboldii* and *Ewersii*. To the above might be added such perennials as *Corydalis lutea*, *Gaura Lindheimeri*, *Stokesia cyanea*, *Polygonum cuspidatum* and *vacciniifolium*, *Statice latifolia*, and many autumn-flowering bulbs, among which may be mentioned *Crocus speciosus*, many varieties of *Colchicums*, *Sternbergia lutea*, *Merendera Bulbocodium*, and others. Some hardy annuals bloom freely during the later months of the year, particularly if they are sown about the end of June or middle of July, and such plants as the *Saponaria* and *Marigolds* keep flowering until cut off by autumnal frosts.—T. S.]

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

***Sparaxis pulcherrima Thunbergii*.**—This beautiful, and by no means common, *Sparaxis* is now flowering well with me in the open border, sending up five spikes of its lovely and most gracefully pendent rose-coloured blossoms resembling the finger of a glove in shape.—W. E. G.

***Suaeda dendroides*.**—This is one of the finest ornamental annuals I have ever seen. Looked at a short distance off, it somewhat resembles a young *Larch*. It is of a fine branching pyramidal habit, attaining a height of between 2 and 3 feet. The leaves are of a glaucous green colour. It forms a beautiful sub-tropical plant.—R. H. B.

***Fuchsias in the Isle of Man*.**—Here these are truly wonderful; they grow up the house fronts, and grow into large trees—so large that you can have a tea-party around the bole of the trees. They are also grown in hedges and kept nicely clipped, and with their bright green leaves and scarlet flowers look cheerful and refreshing; the winds and the spray from the sea do not in the least affect them.—W. NEWTON.

Hutton's Cockscomb (*Celosia Huttonii*).—What means should I use to make this flower? I have sown a lot of sturdy plants about a foot high, but they show no indication of flowering. Is it now too late to expect them to do so? The plants were raised in heat, and have been grown on in a very warm greenhouse, and some seedling *Cannas* raised at the same time, and under similar circumstances, are unexpectedly showing flower.—A. B. [Messrs. Veitch inform us that *Celosia Huttonii* does not flower till late in the season, generally in the latter end of September, after the plants get a little beyond a foot in height. No particular treatment is required to make them flower.]

***Erpetion reniforme*.** This little Australian gem is flowering remarkably well with me this season. As it is not perfectly hardy here, it requires the protection of a cold frame in winter, and to be planted out in May. It luxuriates in peaty loam, and forms compact tufts of reniform leaves adorned with a profusion of blue and white Violet-like flowers. I am sure that all who appreciate modest beauty will thank me for directing attention to this little plant. When grown in pots under glass, it is not nearly so beautiful as when planted in the open border. Well do I recollect the pleasure with which I collected specimens of it, some thirty-five years ago, when wandering among the valleys of the Australian ranges.—J. WHITTAKER, *Morley*.

THE GARDEN IN THE HOUSE.

DINNER-TABLE DECORATION.

Vases for the Breakfast-Table.

On the breakfast, as well as on the dinner, table there should always be at least one vaseful of flowers, and as the breakfast-table is seen by daylight, the decorator has a much larger amount of blooms to select from than is the case when they are to be subjected to artificial light. In summer such decorations should consist nearly altogether of hardy Fern fronds (or, at least, those which will remain fresh for some time after they have been cut) and wild Grasses, with only just a few flowers dotted through them, here and there, to give colour; as the flowers fade much sooner than foliage, they can be removed when necessary, and fresh ones put in their places. Thus a variety of shades of green may be blended together, in such a way as to show up well, in contrast with the white damask cloth. I have seen very charming arrangements made, wholly without flowers, Ferns and other foliage being used alone; but to make these effective is by no means an easy task, and should never be attempted by a beginner, as failure is sure to be the result. A little practice, however, and a good eye for colour, will soon overcome the difficulty. The following is one of the prettiest little ornaments for the breakfast-table I ever put together. The vase which I employed consisted of a soup-plate, and in the centre was a plant of *Cyperus alternifolius*: round the edge of the plate I put a fringe of different varieties of Ferns, some golden ones, so placed as to exhibit the colour on the backs of the fronds; over the surface of the Moss I then arranged sprays of rich purple *Cinerarias*, white *Azaleas*, *Lily of the Valley*, and white *Cyclamens* with purple tips, a few fronds of *Maiden-hair Fern* being interspersed through the whole, and up the slender stems of the *Cyperus alternifolius* ran a few slight shoots of

Vase decorated chiefly with Grasses.

Cissus discolor. Another pretty little vase, but of much smaller dimensions, I have often used during the summer months. It was a simple trumpet of white China resting amongst a cluster of silver rustic branches; in the trumpet I put white Sweet Peas, blue Corn-flowers, a few Fern fronds, and wild Grasses. This style of vase takes but very few flowers (an important point where there are not many plants to cut from); and, for a small-sized circular table, an

arrangement of this kind will be found large enough. The next I shall describe is quite different from any to which I have yet alluded, and is well adapted as to form for either the breakfast or dinner-table, and it would also be found, I have no doubt, to be a very elegant ornament on a side table in the drawing-room, but as the decoration of the breakfast-table is the subject now under consideration, I shall confine my directions to dressing it for that purpose. In each of the tiny tubes grouped round the glass ball in the

Vase ornamented chiefly with Ferns.

accompanying illustration a Moss Rose-bud might be placed, backed up by a few fronds of Fern, while the tazza may be filled with various other kinds of flowers, and the trumpet finished off with a plume of Grasses or Ferns. Any style of floral decoration, indeed, is acceptable on the breakfast-table; for, as a rule, not one in a dozen has a vase of flowers on it, while, on the contrary, one often meets with decorations on dinner-tables that might very well be dispensed with. Whenever possible, however, always have a cheerful vaseful of flowers on the breakfast-table.

A. HASSARD.

Maize as a Window or Balcony Plant.—Maize or Indian Corn has much to recommend it to the notice of window gardeners, being easily grown and readily propagated. Its appearance is quite distinct from that of anything else in the way of window plants, and it will make a luxuriant growth even in the most smoky and densely-populated parts of London. If sown on a genial hotbed in February, and potted on in rich well-mannered compost, young plants of it will be strong and vigorous, and ready to place on the balcony or outside the window, in May. As a central plant for a hanging-basket or rustic stand, Maize is equal to a *Dracaena* in grace and beauty of outline, besides being much more lardy. It grows from 2 to 3 feet high, and its fresh green wavy leaves hang gracefully over the sides of the pots in which it is grown, and do much towards adding variety of outline to the most formal arrangement. There is a variegated variety, the foliage of which is profusely striped with creamy white. This is an effective addition to the centres of vases in which bedding *Geraniums*, *Nasturtiums*, and *Lobelias* are planted during the summer months.—F. W. B.

THE GARDENS OF ENGLAND.

MARTON HALL.

THIS, the residence of H. W. T. Bolkow, Esq., M.P., occupies one of the finest sites in Cleveland. It is of modern erection, in the Italian style, rich in architectural ornament, and is surmounted by a lofty dome, which has become a landmark for ships entering the Hartlepoons and the Tees. The view from the roof, which is flat, can hardly be surpassed as regards extent; right in the foreground the town of Middlesborough, so closely identified with the Cleveland iron trade, sends skywards dense columns of flame that illuminate the midnight sky for miles around. Eastward, at a distance of five miles, is the broad estuary of the Tees, dotted with ships; in the background the ancient town of Hartlepool stands out in bold relief. To the south is the German Ocean; westward stretches Teesdale, rich in natural beauty, with the town of Stockton, standing high upon the left bank of the river, while the Cleveland Hills, so rich in iron ore and other minerals, in all their varied beauty of form and outline, make a fine background to the picture. Here, too, Captain Cook was born; but the cottage in which the event took place has long since been demolished, and a hall, built upon its site, was burned down some forty years ago. This old hall was never rebuilt, and a portion of its ruins, standing within a few yards of the south front of the present mansion, is clothed with Ivy, and shut out from view by means of evergreens and other trees. In making some recent improvements in the ornamental portion of the grounds, several old fruit trees that stood in little gardens adjoining have been wisely spared, and now form interesting objects amidst rare Conifers, purple Beeches, and weeping trees of various kinds. In autumn these trees yield good crops of fruit, besides forming ornaments to the lawn when in blossom in spring. Let us hope that the day is not far distant when the Apple and other fruit trees will find places amongst the ornamental trees that surround even our best English mansions. I was pleased, too, to see that no systematic attempt had been made to destroy the undulations of surface that naturally existed around this fine mansion, by what are termed modern artificial improvements. No flower beds are in close proximity to the residence; on the contrary, the beautiful green sward is clothed over in a very natural manner with endless variety in the shape of graceful trees and shrubs. Amongst other things I observed many fine standard Rhododendrons of the newest varieties. Mr. Hanson, the gardener, informed me that in such dry years as this, water has to be applied freely to these Rhododendrons during the growing season, otherwise their flowers would be small and imperfect. The soil here is naturally dry and light, and well adapted for the growth of Conifers, among which I noticed different varieties of the Lawson Cypress, very fine, particularly that called *C. Lawsoniana erecta*. Different kinds of Japanese Conifers, introduced by Fortune and Veitch, are here in abundance. Nothing can exceed many of them in beauty of habit and richness of colour; indeed, they only require to be seen to be appreciated. The *Retinosporas* are truly charming, varying as they do in colour from the richest green to the most exquisite golden tints. *Juniperus japonica aureo-variegata*, a species of Golden Juniper, bids fair to become an object of great beauty here, as do also many others, such as *Thuopsis dolabrata*, and, considering the time such things have been planted, the progress that has been made by them is wonderful. The same may likewise be said of the Coniferae, planted along the base of the Cleveland hills at the different gentlemen's places, made there within the last twelve years, a circumstance which would seem to support the idea that a soil strongly impregnated with iron is favourable to the growth of Conifers.

The flower garden, which is small, occupies a hollow in the lawn, about 50 yards from the west end of the hall, and a broad terrace from the south front leads to it, past a small conservatory that is attached to the house. A broad avenue leads from the east end to the forcing-houses, which form three sides of a square; running north and south, is an orchard-house, 70 yards long and 18 feet wide, in which the trees are ranged in parallel lines on each

side of a pathway, and its sameness of aspect is relieved by means of the introduction here and there of both foliage and flowering plants. Both in construction and finish this must be acknowledged to be a very superior orchard-house, and, being span-roofed, light is abundant, and the benefit which it confers on the fruit trees is indicated by their deep green foliage, dwarfness, and compactness of growth, as well as by the fine crops which they produce. Mr. Hanson finds Meredith's Vine manure to be excellent for Peaches, Pears, and Plums, and he uses no other stimulant for his trees in pots. Another range of glass, equal in length to the orchard-house, is divided into three compartments, the centre one being devoted to the growth of hard-wooded plants; amongst these were some fine Heaths, Epacris, and Azaleas. Winter Cucumbers are grown in another division, as are also French Beans and other early vegetables. The third division is occupied with fruiting Pines, principally Queens, Black Jamaicans, and Charlotte Rothschild. In the centre of another range are Palms and other plants, among which I observed some fine examples of *Allamanda grandiflora* grafted on the roots of *A. Schottii*. The other divisions in this range are filled with Grapes, Peaches, and Pines. Seldom have I seen a finer crop of Peaches than I found here; one house had just been cleared of fruit, and the foliage looked green and healthy without symptoms of mildew or red spider. Nectarines have also been exceedingly fine, considering the season. The kitchen garden is small and compact, and is enclosed on three sides by the ranges of glass structures; on the walls are some very fine Nectarines and Apricots; standard fruit trees are here kept very dwarf and bear most abundantly, especially Pears, Apples, and Plums; Gooseberries, Currants, and other small fruits seemed to be also plentiful. There is a frame-ground furnished with several forcing pits, in which are grown Melons and Cucumbers in great abundance; in short, nothing has been spared to make the gardens here perfect in every department.

J. THOMSON.

A Good Plea for Public Gardens, &c.—It is all very well (says a "Working Man," in the *Wolverhampton Chronicle*) for the upper classes to talk about abolishing the fairs and the races; it would make no difference to them, as we are quite aware that the gentry think it beneath them to go to such places. They can go to London and the sea-side to amuse themselves; but they should consider that if our amusements are not much to speak of in their estimation, they are the best that are provided for us, and we have to put up with what we can get till we can get something better. For my own part, and many more are of the same mind, I would sooner the races were done away with, if there was a public park for us instead. I should often take my good woman and the young ones there in an evening, instead of going to the "Fox and Goose" or the "Pig and Whistle," where, of course, I should get into company, and out of my money. I should feel as much pleasure sitting by her side drawing a quiet pipe and watching the children romp on the Grass, as my employer does with his cigar in his pleasure grounds looking on while his children are at their games. Many think ill of us because we spend our evenings in public houses; they don't think that working men's houses are very small and inconvenient, and that where there's a family there's plenty for a woman to do, and a man is apt to feel he is in the way; it isn't much pleasure to a man to walk on the road-side over the same ground year after year; and, as for the children—it is true they have the road or street to run about in, provided they keep a sharp look out for horses and cabs, but if they go into a grassy field, where there is plenty of room and no danger, they are pretty sharply ordered out, and it is well for them if it ends there. A people's park would do a good deal for the enjoyment of working men and their families, and now is the time for those gentlemen who tell us that they have the elevation of the working classes at heart, to show it.

The Necessity for Public Playgrounds.—At an inquest held by Dr. Hardwicke on the body of a child who had been run over by a railway van, the learned coroner remarked that, owing to the inaction of the municipal authorities, the metropolis was almost without accommodation for persons to sit or rest, and the same remarks applied to open spaces for children's playgrounds. He advocated the throwing open of the gardens in the squares for certain hours in the day. All children ought to have at least two or three hours, or more, exercise in the fresh air daily. The general public and authorities appeared indifferent to this most important matter, but it was one affecting the future of the country.

HIGH WALLS OF ROCK IN GARDENS.

ACCOMPANYING the rock-works whose penurilities have been so often commented on in this journal, there is frequently an attempt at making a cascade, which is often a complete failure so far as regards the picturesque effect. Forming anything of this nature in connection with artificial rock-work requires much taste and judgment, and the attempt had better never be made than made without such conditions. In public and private gardens, however, there are not unfrequently to be found high masses of natural rock, over which cascades may be conducted with almost the certainty of producing a good

Arabis and Aubrietia. On such walls of rock, Alpine flowers present an appearance as natural and beautiful as on their native cliffs. Another notable mode of embellishing such surfaces is by the planting of free-trailing and climbing plants above, and allowing them to hang down the face of the wall. By this mode one is enabled to show the full beauty and grace of many fine plants, now mutilated on walls. It is easy to find plants that will curtain the rocks for many feet, the main point being to select kinds that will furnish beautiful or fragrant flowers, as well as a profusion of graceful shoots. For the higher parts, such species of Clematis as

effect. And such opportunities should be taken advantage of as often as possible; for, as pointed out in THE GARDEN in spring, some of the most imposing and beautiful waterfalls in existence have been formed artificially by turning the course of running water over high walls of rock; and this is but one of the many beautiful ends to which such walls may be converted. In their seams and patches of earth brilliant rock and mountain flowers may be grown to any extent. As any "preparation of the ground" must be difficult in such cases, the best and simplest way is to sow a good and varied collection of seeds in the chinks and patches of earth in spring and also in autumn, using in this case extremely hardy kinds, like

C. Flammula and *C. montana*, would be admirable; while for the lower parts and low cliffs, the new hybrid varieties would do well. For the base of such walls there is nothing more appropriate than the more vigorous of the hardy forms (native or exotic) of American plants, and some choice and free-growing herbaceous plants. On the crest of such masses, we have one of the best sites for the placing of fine and distinct tree forms, particularly those of bold or pointed habit, like many of the Pines, and some deciduous trees of erect or pyramidal habit. On the lower flanks and fringes rock and mountain shrubs, dwarf American plants, Heaths, and wild Roses should be introduced.

VILLAGE GARDENS AND COTTAGERS' ALLOTMENTS.

EVERY cottager should have a little garden, in which he should be encouraged to take an interest. This might readily be effected—by apportioning out allotments, in the culture of which he shall be subject to certain mildly restrictive rules, and to a periodical inspection, resulting at the close of each season in the distribution of prizes amongst those who have proved most successful in their management. The importance of such a movement has been recently brought prominently under my notice, in connection with a scheme of this sort, which has been ably and practically carried out at the village of Brantingham, some twelve miles distant from Hull, by Mr. Kingston, gardener to Christopher Sykes, Esq., M.P.; and so much impressed am I with the value of the results, that I have no hesitation in submitting to your readers a general outline of the mode of procedure, which has now, as the result of considerable experience, received such modifications as practical working through a series of years can alone give. Having myself assisted in the adjudication since the commencement, I can with confidence bear testimony to the important change which has taken place in the appearance of the village. Nor is the improvement confined to the gardens and allotments alone, but extends its influence to everything about the cottages; neatness and order pervading the whole of the out-buildings. Surely, therefore, I cannot be wrong in thinking that the healthy stimulant which a competition gives may find numerous emulators through the country. In many cases (as in the one I allude to) nearly the whole village is the property of the squire, whose residence adjoins thereto. In that case the expenditure of a few pounds by the owner, and a little organisation and trouble on the part of his gardener, will lead to invaluable results. But its advantages are by no means confined to small villages alone. Where the owners are numerous, what easier than to form a society—a horticultural society in the truest and highest sense of the word, as distinguished from a “flower show society?” There are towns in which allotments may be counted by hundreds, and even tens of hundreds, where the stimulant of competition has never been thought of. Surely the landlords, who are receiving a double return in the shape of a good rental and a thorough working of the land by spade labour (in the highest degree conducive to its permanent improvement), would find it—setting aside even philanthropic motives—to their interest to contribute to a prize fund, and to any expense incurred in the competition; nor do we think the tenants themselves would object to add their quota in the form of an entrance fee or such like. Tastes vary; some of the allotment holders may have a partiality to flowers; others to fruit and vegetables; others, again, to the more marketable commodities in the way of Potatoes, Carrots, Turnips, &c., all of which have a ready saleable value in the neighbourhood of large towns. These variations would obviously lead to a system of classification, each separate group competing within itself. An important point in all such competitions, and one followed out in the case in question, rests on the fact that adjudication is not the result of one inspection, but of three periodic inspections; thus, as it were, keeping the interest continuous during the season. And, what is more, the services of a different set of judges for each inspection might readily be secured, thus avoiding even the possibility of favoritism. Though at first sight this change of judges may appear impracticable, yet it is easily worked by fixing a certain numerical value to the various gradations of excellence—such as bad represented by one; moderate by two; good by three; very good by four; excellent by five. The sum total of the three adjudications will generally be found to reduce the numbers amongst the competitors to a very small limit, and not unfrequently to leave the best tenant alone as master of the situation. Were the competition on a very extensive scale, possibly it would be best to use numbers alone; the various gradations, from bad to excellent, being represented by numbers extending from one to ten. This system of having a standard to work by obviates the necessity of attempting the impossible task on the part of the judges of carrying in the mind's eye the various perfections or imperfections of each of the competing gardens. In competitions of this class, it would be necessary to remunerate the judges; but in villages there are always able men for the purpose to be found in the gardeners of the neighbouring gentry, who would willingly give their services for this purpose, and consider the stimulus to horticulture and the benefits they thus assist in conferring on their fellow-men ample reward for their trouble. Possibly it may interest your readers to give an illustration of a bit of originality I noticed on the occasion of my last inspection of the gardens at Brantingham. The season just passed has been unprecedented for its dryness, and, indeed, general ungeniality for anything like a floral display. The soil in the neighbourhood is of a somewhat sandy nature, the village lying at the base of a ravine occurring in the chalk hills, drying to an uncomfortable-looking whitish crust even soon after it is watered.

Some little distance therefrom there is a boggy locality, with soil almost ebony black. Now, a happy thought suggested itself to one of these cottagers to use this black soil as a top dressing amongst his plants; and what was the result? That the golden hue of his variegated Geraniums and his Thyme was doubly intensified; that the silvery purity of his *Cerastium* border was rendered more silvery by contrast; and that, while bringing out the beauty of the colour, the black bog soil answered the purpose of a mulching, whereby the moisture was retained in the soil as effectively as by the use of those unsightly materials that are generally recommended for this purpose. Here is a wrinkle for my gardening friends worthy to be chronicled far beyond the boundary even of our big county of Yorkshire. So much for originality. Now let me give an illustration of the change which may be made—or perhaps I ought to say the result which follows a competition of this sort. Last year there was adjoining one of the cottages a somewhat commodious pigsty, measuring perhaps 8 feet by 12 or 14 feet. The cottage was undergoing repairs, and consequently tenantless. The sty was empty, and had been so for some time, as there was a most luxuriant crop of Docks and Nettles therein. This year the scene is changed as if by fairy wand; the pigsty has been removed some distance to the rear of the house—and very properly too; and, in lieu of Nettles and weeds of all sorts, a flower bed almost as perfect as those even in Battersea Park presented itself, the boundary wall covered with creepers, growing and flowering as freely as their predecessors (the weeds) had done, and the little garden a very model of beauty, originality, and industry combined. This is a mere sample of what changes may be worked out by calling into play a wholesome competition.

A novel feature was introduced into our village gardens this year for the first time, in the addition of a spring flower competition, as represented by class 4. At the adjudication of this, which took place in Easter week, I was unable to be present, but have since learned that the result was quite as satisfactory as attends the wonted summer competitions, the little gardens being gay with Wallflowers, Violets, Pansies, Daisies, Feverfew, and Forget-me-nots, all plants readily and cheaply accessible to the cottagers. If not encroaching too much on your space, I would ask you to kindly insert the rules and regulations, as well as the classes, as defined, and prizes awarded in each class; the former may require slightly modifying to suit local peculiarities, but the principles will remain the same.

JAMES C. NIVEN.

Hull Botanic Gardens.

The following are the rules and regulations:—

1. The allotments shall be let from year to year. Six month's notice shall be given at Michaelmas to leave at Lady Day only. The incoming tenant shall take possession on the 1st day of February.
 2. Every tenant shall pay for the Ringbeck Allotments twelve shillings per year, for the Wooddale Allotments fifteen shillings per year, in half-yearly payments, the first Monday in May and the first Monday in November.
 3. Every tenant shall cultivate the land by spade husbandry only. He shall not be allowed to use a plough or any agricultural implement; nor shall he be allowed to grow more than one-third Corn or Carrots, or two-thirds Potatoes at those rents. Any tenant breaking those regulations shall be charged double rent.
 4. On no account shall any tenant be allowed to underlet his allotment.
 5. The examination of classes Nos. 1, 2, and 3, shall be made three times during the season—viz., in Trinity week, the third week in July, and the first week in September.
 6. The examination of class 4, for spring flowers, shall be made in Easter week.
 7. The examination of Hollyhocks shall be made the second week in August.
- Class 1. For the best managed and best cropped allotment garden.—1st prize, 18s.; 2nd prize, 14s.; 3rd prize, 10s.; 4th prize, 7s. 6d.; 5th prize, 5s.
- Class 2. For the best managed cottage vegetable and fruit garden.—1st prize, 18s.; 2nd prize, 14s.; 3rd prize, 10s.; 4th prize, 7s. 6d.; 5th prize, 5s.
- Class 3. For the neatest and best kept cottage flower garden in Brantingham.—1st prize, 15s.; 2nd prize, 12s.; 3rd prize, 8s.; 4th prize, 4s. 6d.; 5th prize, 2s. 6d.
- Class 4. For the cottage flower garden having the best show of spring flowers during Easter week.—1st prize, 6s.; 2nd prize, 5s.; 3rd prize, 4s.; 4th prize, 3s.; 5th prize, 2s.
- Class 5. For the best four distinct kinds of Hollyhock.—1st prize, 6s.; 2nd prize, 5s.; 3rd prize, 4s.; 4th prize, 3s.; 5th prize, 2s.

THE SHAKESPEAREAN GARDEN.

The Lily.

THE name of the Lily, like that of the Rose, originated in the remotest times, and like the latter again, is probably traceable to some primitive Aryan word. Whether in the beginning it held the etymological sense of whiteness, there is, at present, no positive evidence, but the probability is certainly in that direction; legend and tradition, and the customs of language, having always associated the two things, and employed the Lily, moreover, as a counterfoil to the Rose, when a metaphor was wanted for red and white. At times, indeed, we find Lily and Rose used as convertible terms, one of the old names of the common white, or the Madonna Lily, having been *Rosa Junonis*.* When reading of Lilies, therefore, in an ancient author, and of the Narcissus, and even of the Rose, it is essential to bear in mind that the words sometimes occupy each other's places. To disserve the two names, Rose and Lily, as used in fable, tradition, and poetry, and to dissolve them out of the still broader idea of "Flower," is in truth almost impossible. There is something very beautiful in the association, something that seems to go a great deal deeper than appears on the instant.

Which of the Lilies were in earliest cultivation, and were familiar to the lovers of flowers in the time of Shakespeare—is a matter not difficult to decide. Numerous as the additions have been in modern days, none were brought to Europe between the time of the Romans and the year 1629, when the *Lilium canadense* was received from North America. The common *L. candidum*, or Madonna Lily, is the only species having white flowers with which they were acquainted. They had noticed, however, the scarlet Martagon, commonly called the Turban or Turk's cap Lily; perhaps also the spotted or purple Martagon, the pomponium, and the orange-coloured and erect-flowered bulbiferum. Pliny, who seems to follow Dioscorides, enumerates three kinds; the white (which is clearly the *candidum*), a purple, and a red, which last he says is Syrian; and by this he no doubt intends the Turk's cap, by Linnaeus named *Lilium Chalcedonicum*. With the early gardeners of Western Europe the coloured species, like the white one, appear to have been great favourites, and the eyes of Shakespeare no doubt rested on them in summer mornings—the splendid *Chalcedonicum* in particular. Bauhin registers this one as *Lilium byzantium miniatum*; Parkinson calls it the "Red Martagon of Constantinople." It is a glorious plant, the blood-red and pendulous flowers, which vary in number from two to six, having the petals so much recurved that when fully expanded the blossom becomes nearly spherical. The native countries are Greece and the Ionian Islands; it is vaguely ascribed also to Persia and Asia Minor, but chiefly, it would seem, upon horticultural tradition. The spotted or purple Martagon, the *L. Martagon* (Linn.), called by Clusius and Dodonæus *Lilium sylvestre sive montanum*; by Bauhin *Lilium floribus reflexis montanum*, and by Camerarius simply Martagon, is at once told by the colour, which is different from that of all other Lilies yet discovered; also by its large and almost pyramidal cluster of bloom. The petals are copiously spotted with purple of a deeper shade, and bend back like those of the *Chalcedonicum*, but not so thoroughly. In the wild state it is the commonest of the European species of Lily, stretching from Spain and France all through the central and southern parts of the Continent. It steps even into Siberia, and is figured in "English Botany" as British. The pomponium, or Pyrenean Lily, is allied to the *Chalcedonicum*, and in some respects resembles it, but the leaves are narrow and scattered instead of broad and verticillate; while the flowers are either red or yellow, with black spots. Lastly, the bulbiferum, or common Orange Lily (called by Bauhin *Lilium purpureo-crocenum*, and figured by Parkinson as *Lilium aureum*) is told immediately by the flowers being perfectly erect, and by the deep orange-red petals being studded on the upper surface with small projections. It is indigenous to Austria, France, Italy, and Switzerland, and, by the time of Queen Elizabeth, had become very widely diffused by florists and cultivators.

The *Lilium candidum*, the Lily *par excellence*, extends, in

the wild state, throughout the southern parts of Europe, from Corsica to Greece and Turkey. Whether it has ever been found wild in Syria, or anywhere in south-western Asia, or elsewhere, is extremely doubtful. The tall, stiff, and upright stems, 2 to 3 feet high, more or less clothed with leaves that are neither large nor small, and terminating in a noble and well-balanced cluster of five or six pearly white bells, that are neither pendulous nor erect, the spotless petals, smooth upon both surfaces, curving outwards with perfect grace, might well establish it as the empress of its order. Its stateliness it may be rivalled by some of the splendid peacocks of the far east, but none, even of the Japanese Lilies, can surpass it in *tout ensemble*, aided as this is by golden anthers, and an odour like that of the Rose. We never need hesitate in accepting this as the Lily intended whenever the term was used with knowledge of the plant, and in the special sense. The early botanists were content to call it *Lilium album vulgare*. Virgil, fifteen centuries before, called the flowers simply *grandia Lilia*, *Lilia alba*, and *Lilia candida*.* With Horace, they were fast-fleeting Lilies;† with Propertius, fair Lilies, and shining Lilies, and silver-white Lilies.‡ Tibullus says the young Roman ladies twined them with *Amaranth*s to form chaplets.§ Hyllonome, in Ovid, wears white Lilies in her hair.|| Shakespeare's Lily, when he used the word specifically, was no other. Thus,

Now by my maiden honour, yet as pure
As the unsullied Lily.¶

And in King John:—

Therefore to be possessed with double pomp,
To guard a title that was rich before,
To gild refined gold, to paint the Lily,
To throw a perfume on the Violet,
To smooth the ice, and add another hue
Unto the rainbow, or with taper light
To seek the beauteous eye of Heaven to garnish,
Is wasteful, and ridiculous excess.**

"To paint," in this admired passage, does not, as in the colloquial, imply the addition of colour, much less a surcharge of crimson or yellow. Just as "purple" denotes brilliant, so to paint is metaphorically, to enrich or adorn. The use of the word in this sense is exceedingly ancient. Plautus, the old Roman dramatist, 200 B.C., applies it to the strewing of the ground with flowers. Cicero, B.C. 52, to the employment of picturesque and expressive words. Chaucer describes

A garden full of leavés and of flowers
Which May had painted with his softe showers. ††

Amid many other passages, to quote which is unnecessary, take just one more, the tender simile in Henry VIII., when the unhappy Katherine forebodes her fate:—

Would I had never trod this English earth,
Or felt the flatteries that grow upon it!

* Shipwreck'd upon a kingdom, where no pity,
No friends, no hope; no kindred weep for me,
Almost no grave allow'd me: like the Lily
That once was mistress of the field, and flourished,
I'll hang my head and perish ††

"Field," of course, is here used in the large and collective sense which it bears in the language of heraldry, not intending a meadow or pasture, but a productive surface, no matter of what tincture; while the "once" refers to the brevity of the flower's endurance. We might almost fancy that in penning these mournful lines, Shakespeare had before his heart the celebrated passage in the musings of Job. "Man that is born of a woman is of few days, and full of trouble. He cometh forth like a flower, and is cut down: he fleeth also as a shadow, and continueth not."§§

The Crown Imperial.

Occasionally, Shakespeare employs the term Lilies in the broad or general sense. In the Winter's Tale, for example,

Bold Oxlips, and
The Crown Imperial; Lilies of all kinds,
The Flower-de-luce being one. |||

The context seems to indicate that having mentioned the

* Georgic, iv. 131. † *Æneid*, vi. 709; xii. 68. ‡ *Odes*, i. xxxvi. 16. § *Elegies*, i. xx. 37; 2, xiii.; 5, iv. 25. § *Elegies*, 3, iv. 33. || *Met.* xii. 111. ¶ *Love's Labour Lost*, v. 2. ** *Act* iv. scene 2. †† *The Franklin's Tale*, 235. ‡‡ *Act* iii. scene 1. §§ *xiv.* 1. ||| *iv.* 3.

* See Gerarde's Herbal, p. 130.

Crown Imperial, he bethought himself that it was a Lily, and that other flowers it was customary so to designate must be mentioned as well. That it counted as a Lily in the Shakesperian age, is plain from Parkinson, for although this writer's "*Paradisus Terrestris*" was not published till 1629, the names he employs must needs, in such cases, have been established ones and retrospective. The same remark will, of course, apply to the names quoted from Bauhin, whose "*Pinax* (literally Index or Register) *Theatri Botanici*," containing all the names which up to the Shakesperian period, had been applied to plants and flowers, appeared only in 1623, or not until seven years after Shakespeare's decease. Forgetting his fealty to the candidum, "the Crowne Imperiall," says Parkinson, "for his stately beautifullnesse, deserveth the first place in this our garden of delights, and to be entreated of before all other Lilies." Clusius had already called it *Lilium persicum*, and Bauhin, *Lilium sive corona imperialis*. By the ancients it is not mentioned, though being a native of Persia, it could hardly have escaped notice. Not indeed, until 1576, does it appear to have been brought to Europe. In that year it was introduced into the royal gardens of Vienna, and very shortly afterwards it found its way to England, being included in the Catalogue compiled by Gerarde. Nature produces few plants more remarkable. The leafy stem is 2 feet high. At the very summit is a tuft of erect green leaves, similar to those which proceed from the root. Immediately below the tuft, is a ring of Tulip-like and pendulous flowers, which are either yellow or copper-coloured; and at the base of every one of the six large petaline pieces that compose them, is a white and concave nectary, from which, when the bloom is in perfection, depends a drop of honey. Looking into the flower, as one would look into a bell, it seems to possess six great round eyes carved out of pearl. G.

A PLEA FOR A MORE NATURAL ARRANGEMENT OF BOUQUETS, &c.

HE must must have an artist's eye for colour and form who can arrange a hundred flowers as tastefully, in any other way, as by strolling through a garden, picking here one and there one, and adding them to the bouquet in the accidental order in which they chance to come. Thus we see every summer day the fair lady coming in from the breezy side-hill with gorgeous colours, and most witching effects. If only she could be changed to alabaster, was ever a finer show of flowers in so fine a vase? But instead, allowed to remain as they were gathered, the flowers are laid upon the table, divided and re-arranged on some principle of taste, I know not what, but never regain that charming naturalness and grace which they first had. As to the bouquets put up for market, the less said about them the better. They are mere pillories in which, like innocent children put into the stocks, flowers are punished! Squeezed, tied on sticks, formal and pedantic, the flowers lose their rare charms, their delicacy, their individuality, their exquisite variety of form, every element of floral beauty except colour. They are used as mere pigments. They are poor studies in colour. With what complacency can such a one look upon the merchandise of flowers which is exhibited at every party, every wedding, every congregation of rich people, who torment themselves through untimely hours for the sake of tormenting their host? Look at the atrocious bridal bouquets! If, instead, the bride were to issue forth bearing in her hand a sprig of Orange-blossoms just as it was plucked from the branch, or two or three simple Rose-buds on the one stem, loosely clustered, and with their own fresh green leaves, or a simple white Lily, would not every one feel how superior flowers were for such an occasion, in their own simplicity and individuality, than when, as generally happens, they are smothered up in an artificial heap, in which all naturalness is utterly lost? A single blossom of Carnation with a Geranium leaf; an exquisite Safrano Rose-bud just beginning to open, with a fresh leaf from its own bush for company; a stem of Mignonette, girt round with a dozen fragrant blue Violets; a long sprig of Murrandia Creeper, with its charming blue bells, hanging from a tall wineglass, or carelessly trailing round it,—these, and such little things, confer a pleasure on those who have a sensitive eye for grace and simplicity, which the formal and pudding-like arrangements cannot. We would not be understood as objecting to all masses of flowers, nor to large combinations. For coarser and more distinct effects, they are permissible. But even then, the more they can be made to have a loose, airy, open habit, the finer will be their effect. But first, simplicity, naturalness, singleness, and individuality in flowers.

H. W. BEECHER.

GARDEN DESTROYERS.

Wasps' Nests in Trees.—Are the wasps which have nests in trees a different species from those in the ground? Or has the difference of season anything to do with the position of nest? I ask because during the last two years, when the summers were wet, I do not remember seeing a nest in a tree, but plenty in the ground. This year with a dry summer, I have seen the proportion of three of the tree kind for one of the ground ones as yet.—A. D. C. [There are two sections of British wasps, called respectively "ground wasps" and "tree wasps;" of each section there are three species. *Vespa vulgaris*, *V. germanica*, and *V. rufa*, belong to the first section; and *Vespa arborea*, *V. sylvestris*, and *V. norvegica* belong to the second section, and build their nests in trees and bushes. The plan of construction of these latter nests corresponds with that of the ground wasps, but they seem firmer in texture, and are certainly more capable of resisting the effects of weather; they are impervious to rain, and are so securely fixed among the branches and twigs that the wind however boisterous, has rarely any effect on them. The species to which your query more particularly applies is *V. norvegica*, which has been abundant this year in Scotland—perhaps owing to the drier weather, as you suggest. The young nests, if we may so denominate them, are beautiful and interesting; we have seen some about the size of a tennis ball, constructed among the wiry twigs of the Ling in such a manner as to ensure their safety. This species and its nest appear to have been found at a very early period in entomological science. Fabricius gave it the name of *Norvegicus* because the specimen which he described, then in the cabinet of Mr. Lund, was labelled as from Norway; see "*Species insectorum*," vol. i., p. 460. Many years afterwards it was re-described by Dr. Leach in his "*Zoological Miscellany*," vol. i., p. 111, and is so well figured on pl. 50, male, female, and neuter, that there cannot be a doubt of the species. The nest figured there is still in the British Museum, and is labelled "taken near Edinburgh." Dr. Leach named the insect *Vespa britannica*, evidently in ignorance of the earlier name. It is by no means uncommon. We have found nests of this species as large as a man's head in a garden at Leominster; they are built in the branches of several species of Conifer, and also sometimes in Gooseberry bushes. In addition to the authors above named, Villars, Olivier, Ponsér, Zetterstedt, and Smith seem to have been well acquainted with it. We need scarcely add, after saying so much, that the peculiar situation of the nest is dependent on the species of insect, and by no means on the season.—ED. FIELD.]

Destruction of Wasps.—Never in my experience can I remember such a plague of wasps as we have had this season; and, if as numerous elsewhere as here, much valuable fruit will be devoured by them. I have found the following simple and safe method of destroying their nests: procure say half-a-pound, or less, of cyanide of potassium; dissolve this in just sufficient boiling water to cover it, then have in readiness some cotton wool, and proceed to where the nests are; saturate a small portion of wool in the poison, then with a stick deposit it at the mouth of the hole, slightly pushing it inside, the entrance must be nearly stopped with the wool; this done, in half-an-hour's time, safely dig out the nests and smash them up. Some nests may require a second dose, but that will be but seldom, if well done at first. Anyone unacquainted with their habits, will be surprised at the number of queens to be found in a nest in October, whereas the workers and males grow weaker and die; and before the end of the year scarcely one will be seen. A few queens will remain at the bottom of the nests, others will take to buildings or any warm sheltered place, wherever that may happen to be, and, in a state of lethargy, they will often pass through the dreary months winter, but, immediately on the approach of warm spring weather, they become re-animated by the heat, and will then issue from their retreat, and seek to find out a suitable place in which to establish their nest. I ought to have said that as soon as the cyanide is dissolved it should be put into a bottle, and be securely corked and labelled dangerous poison.—J. EASTER, in *Gardener's Record*.

NOTES AND QUESTIONS ON GARDEN DESTROYERS.

Pear Slugs.—These are, as usual, abundant and very destructive. They are, however, readily destroyed by dusting the leaves with lime, ashes, or even fine dry road dust, which adheres to the slimy coat of the slugs and soon kills them.

Ants and Chalk Marks.—A chalk mark, at least half an inch in breadth, around the upper edge of sugar buckets, barrels, &c., will not admit one and into their interior. The same mark drawn on the edges of shelves will also prevent the approach of an ant, as they are not able to crawl over the chalk.—C.

Earth Worms in Pots.—A correspondent of *Vick's Floral Guide*, who had been much annoyed with earth worms in pots, succeeded in eradicating them by watering with ten drops of carbolic acid added to a pint of water. It operated like a charm, killed all the worms, and the plants began to improve at once.

THE ARBORETUM.

A BEAUTIFUL SHRUB.

(RHODOTYPUS KERRIOIDES.)

In passing through Paris, on May-day of the present year, the shrub which most of all attracted our attention for its novelty as well as beauty, was *Rhodotypus kerrioides*, of which the subjoined is a representation. The illustration reminds one of the single *Kerria*, but as the flower is pure white, the distinction is sufficiently obvious. The flowers are abundantly produced on a graceful-looking shrub, about 3 feet high; the plant is quite hardy; it is easily increased by cuttings, and sometimes by separation of the suckers. In favourable seasons it begins to flower about the middle of April, and continues to bloom

Rhodotypus kerrioides.

throughout the month of May. It comes from Japan, and we know of no subject more worthy of a place in the flower-garden or choice shrubbery.

PLANTING AND MAINTAINING OF UNDERCOVER FOR GAME.

By W. GILCHRIST.

THE planting and maintaining of undercover for game is so closely allied to the general management of plantations, that it is impossible to consider it aright without taking a summary survey of the following subjects connected with arboriculture;—

1. Planting and thinning of young plantations.
2. Thinning, draining, and planting undercover in old plantations.
3. Plants best adapted for undercover.

I.—Planting and Thinning of Young Plantations.

The ordinary method of rearing young plantations where game are numerous is to plant close and thin early, regulating the distance apart according to the soil and situation, also the size and kind of trees to be planted. As a general rule, 2½ or 3 feet apart is wide enough in exposed situations, and 3 to 3½ feet apart where the soil is good and the situation sheltered, or even 4 feet apart if the plants are large. Where there is no game, or where the young plantation is protected from the ravages of game, the young trees may be planted at from 4 to 6 feet apart, according to the soil and situation. This last mentioned method is perhaps the best, where the young trees,

after being planted, are left entirely to themselves until they are fit to be used for stobs, or some other estate purpose; for if they were planted close, and left unthinned until they were suitable for some estate purpose, the most of the young trees would receive a check from which they would never thoroughly recover. To this cause, viz., planting close and neglecting to thin in due time, may be attributed the stunted, overdrawn, and unhealthy appearance, and consequent absence of undercover, which a great many young plantations present. However, I have invariably found, that to plant close and thin early, hardly ever allowing the lateral branches of one tree to touch another, is the only sure way to rear healthy trees, and form good undercover. And one great advantage to be derived from planting close is, that in thinning the first and second time, the healthy plants requiring to be taken out may be lifted with balls, and used for making up wants in young plantations, or forming clumps of undercover in old plantations. No definite rule can be given for the thinning of young plantations, or for the time that should be between the first and second thinning; all this can only be determined after a careful examination of the plantation. But, in general, young plantations, if healthy, will require to be looked over, and a few trees taken out, or a little pruning done every third or fourth year.

Young plantations are sometimes required to be formed and reared, not so much for their value as a crop of trees, but for the purpose of affording protection and shelter to game; and where this requires to be done, we would recommend that the young trees be planted about 6 feet apart, and intermixed with low-growing underwood—such as the Bramble, Broom, and common Whin. The two latter varieties are generally raised by sowing seed in rows, which intersect the young trees both ways. Before sowing the seed the ground must be prepared for its reception. This is done by digging the ground about 6 inches deep and 12 inches broad, leaving it rough on the surface so as to get the seed thoroughly covered. In situations where underwood suitable for cover is found growing natural it should be taken advantage of and cultivated in preference to all others; and, when the soil is suitable, the young trees used should be all evergreens—such as the Scotch Fir, Spruce, and Silver Fir, Austrian, Corsican, and Mountain Pine, and the underwood, though growing among them, should always be kept in check, and not allowed to get overdrawn or to grow too near the young trees. This system of rearing undercover is very extensively practised in some parts of England, where it is esteemed, both for its usefulness and cheapness—two very essential considerations in the providing of undercover.

Young plantations are sometimes formed in the demesne or pleasure-ground, for the threefold purpose of shelter, ornament, and game-cover. Where this requires to be done, a selection of ornamental trees and shrubs will require to be used, and in this promiscuous planting of trees and shrubs, whether in the park, the pleasure ground, or the forest, much attention requires to be given to the individual character of each variety to enable the planter to arrange them so as to bring out their most prominent features in the landscape, and, at the same time, preserve the individual character and appearance of each variety; for whether it be a clump of shrubs, group of trees, or single specimen, the effect which is produced by judicious arrangement is very remarkable. No definite rule for the arrangement of the plants can be given, as a good deal depends upon the nature of the ground, situation, and exposure. Where the situation is sheltered, the young trees may be larger, and planted farther apart, and the shrubs used for undercover should also be proportionately larger. The low-growing shrubs, such as the evergreen Privet, Mahonia, common Laurel, Rhododendron, &c., should be planted in clumps, with perhaps an upright-growing tree, or a Cupressus, in the centre. The Scotch Yew, Portugal Laurel, Holly, and the deciduous shrubs, should be used as nurses for the trees, and for this purpose, as well as for the benefit of the game-cover, they will require to be occasionally cut to prevent them from getting overgrown. The deciduous shrubs that are of a straggling habit, such as the Dogwood, Ribes, and Elder, should be kept in the background, while the Snowberry and Spirea should be kept nearer the front. The Holly and Elder should be planted in the exposed parts, and nursed with Beech or Sycamore; the Beech makes a capital nurse, as, if cut and kept low, it retains its leaves during winter; the Scotch Fir and Austrian Pine are also well adapted for growing in exposed situations. Clumps of Rhododendrons and Azaleas should be planted along the sheltered sides and rides, with occasionally a single plant of Scotch Yew, Holly, Portugal Laurel, or some of the deciduous shrubs. For the sake of variety, low-growing weeping trees, such as the Kilmarnock Willow, are also admirably adapted for this purpose. In fact, where shelter, ornament, and game-cover is the object, the dwarf trees and shrubs should be planted nearest the front, and the taller ones in the background, and the contrast of size, form, and colour of the different varieties will then show to the

greatest advantage. In a plantation of this description, where hares or rabbits are numerous, some of the shrubs and hardwood trees will require to be protected from their ravages, and for this purpose a quantity of small Spruce branches should be prepared. Have boys following the planters, and put in three or four branches closely around each plant, and bind them together with rope-yarn. In preparing the branches they should be cut with a slant, so as to go freely into the ground. We have practised this method for a number of years, and have found it to be the cheapest and most effective way of protecting shrubs and hardwood trees from the ravages of these animals. In maintaining a plantation of this description, the shrubs must be kept low, and prevented from getting into a confused mass. The trees should be kept thin, and the evergreen ones allowed to remain green and branched to the ground, as it is their natural form, and affords the best shelter and protection to the game.

II.—Thinning, Draining and Planting Undercover in Old Plantations.

What I wish to be understood by the term old plantations, is plantations from thirty or forty years old and upwards. Plantations of this description are to be found on almost every estate; and unless where they are chiefly composed of Firs, and have been under good management, they are generally devoid of undercover, although some of them possess plants suitable for that purpose, such as the Black-thorn, Bramble, Briar, wild Raspberry, Broom, common Furze, Birch, Willow, Hazel, and other natural copsewood plants; but instead of these plants, which are naturally adapted for undercover, being kept in check, they are generally found striving for the mastery over the standard trees, and preventing the free circulation of light and air, thereby impairing the health of the trees, and deteriorating from their value as a crop.

Plantations of the above description only require to be judiciously thinned, and the overgrown underwood cut close to the surface, and the ground thoroughly cleared (by burning or otherwise) of all brushwood or decayed branches, also the drains cleaned and new drains made where necessary, and in two years the undercover will be in a condition to please the most fastidious sportsman. In corroboration of this statement, I will give a description of a plantation that came under my notice a few years ago. It consisted principally of hardwood trees, about fifty years old, a full crop of which was on the ground, plants naturally suited for underwood were also in abundance, but they were so much overgrown, that they had become quite open and bare below. As brushwood was required for estate purposes not far from the plantation, the whole of the underwood was cut close to the ground and the best of it taken away. Immediately thereafter, the trees were regularly thinned, and the ground thoroughly cleared of all brushwood and branches; these operations were done in the summer season, and in the month of December following, when the gamekeeper and proprietor went through on their annual shooting excursion, they agreed that, however bad it was before, it was now thoroughly spoiled; however, the following season, the underwood and natural Grasses had grown so well, that they as unanimously agreed that they had never seen the undercover of any plantation so much improved. The successful growth of the undercover in this plantation was entirely owing to the brushwood and branches being cleared away, thereby allowing the light and air to have free circulation, and causing the natural Grasses and the shoots from the underwood to grow freely at first; seeing that clearing the ground of the brushwood and branches is so beneficial to the maintaining of undercover, it is very much to be regretted that, in thinning plantations that are overgrown with underwood, the common practice is to spread the brushwood and branches all over the ground. This practice, though common, is very detrimental to the maintaining of undercover, as there is no surer way to stop the growth of underwood than to cut it close to the surface and leave the brushwood spread over the ground.

Plantations with a full crop of trees, but no underwood suited for cover, and in plantations of this description cover for game must be provided artificially. This is generally done by planting such plants as are considered suitable for undercover, and in some instances, where the plants are well selected, and the ground thoroughly prepared, the system produces the desired effect, but a much less expensive and surer method of obtaining cover for game in plantations of this description is to give the trees a regular thinning, and afterwards gather together all the branches and brushwood, and put them up into heaps about 4 to 8 feet high, and 10 to 18 feet in diameter. These heaps are erected by driving a stab into the ground, and putting the shortest of the branches round about it. For the sake of stability, these short branches should be pointed and stuck firm into the ground. Keep the branches close at the top and open below, using the larger branches as the work proceeds, and turning them end for end alternately, so as to get the points of some of the best furnished branches

to the ground. In finishing, have the branches spread well out and rather flat, so as to allow Grass to grow up through them in the summer season (for it must be remembered that there is no better cover for hares than good natural Grass); and the branches being laid nearly flat, keep the Grass up during the winter. These artificial heaps are sometimes formed round the bolls of the trees; and near the outside of plantations to break the view, and also near to the places where the pheasants are fed. A few well-furnished branches or tops should be pointed and stuck into the ground, in places where there is the appearance of low-growing underwood, such as the Honeysuckle and Ivy, as they grow up through the branches and form nice clumps of cover, which are generally very productive of game when the shooting day comes. If there are any small Beech or Thorn trees growing in the plantation, they should be cut half through, about 2 or 3 feet above the ground, and laid down flat. These trees being only cut half through, continue to grow, and have all the appearance of low-growing underwood; and though at first sight they are not very pleasing to the eye, they soon come to be useful for game-cover.

This method of forming and maintaining undercover for game is considered by all who have given it a fair trial to be the surest and most economical way of providing undercover in plantations, where there is no natural underwood suited for that purpose; and its beneficial effects are realised in one year by the increase of game, as in a portion of a plantation on the estate treated in this manner the increase of game in one year was seven-fold. It is also specially adapted for outlying plantations, where there is a full crop of trees on the ground, as it can be renewed every time the plantation is thinned; in fact, the branches of every tree that is cut should be put neatly up into heaps to maintain the game-cover.

Old plantations, where there is not a full crop of trees on the ground, and also a deficiency of plants naturally suited for undercover.—Some practical men may consider that the best way to make a plantation of this description a good game-cover is to cut it down and replant it; and, no doubt, where the trees have almost arrived at maturity, looked at from a pecuniary point of view, this would be sound practice; but in a great many instances, and more especially on small estates, these old plantations are not valued by the ordinary rule of pounds, shillings, and pence, but they are valued and prized for the shelter they afford to the adjacent lands, and the beauty and ornament they impart, not only to the estate, but to the whole of the immediate neighbourhood. Where plantations of this description have been under good management, no thinning will be required farther than taking out any trees that may seem to have arrived at maturity. On the contrary, where they have been neglected, they will require to be gone over and thinned very carefully, leaving the healthiest and best furnished as standard trees, and taking out all such as are overdrawn, or are encroaching too near any of the standards, and also all those that are stunted in growth and have an unhealthy appearance. As we are presuming that there is not a full crop of trees on the ground, there will probably be some portions where the trees will be too close, and other portions where there will only be a tree here and there, so that in thinning it will be better not to attempt to have the trees at regular distances from each other, but rather have them in groups, and clear out the open spaces of the ground so as to get good large clumps of trees or shrubs planted to form undercover. After the trees are cut, the best of the branches should be gathered and put up in heaps (as formerly described) where the trees are closest, after which the brushwood should be burnt and the ground thoroughly cleared. If it is not necessary to use the branches to form undercover where they are cut, they should either be burnt or carted away to some plantation where they are required.

Before proceeding to plant any undercover all the old drains should be examined and cleaned out, and new ones formed where they are required, after which the planting of undercover may be proceeded with; and, in selecting the varieties of plants to be used, the planter will generally be guided by the wishes of the proprietor and by local circumstances, such as whether plants of a suitable size and variety can be had in the district at a reasonable outlay. Some recommend the planting of deciduous plants, such as the Hazel, Birch, Willow, Mountain Ash, &c., and cutting them down regularly when they are fit for cratemarkers' or other purposes. This system of rearing underwood may realise a little money; and, no doubt, in plantations where deciduous plants are growing naturally, or as coppice woods, they make admirable undercover if well managed; but, nevertheless, it is impossible for undercover formed chiefly of deciduous plants to afford the same protection to game, or have the same clothed appearance, as where it is formed with evergreen plants. Therefore, we would recommend that, wherever undercover requires to be planted, only evergreen trees and shrubs should be used, except where a variety of plants are required for ornamental purposes. Our own method of

forming undercover in plantations of this description is to plant large clumps in some of the open spaces, with well-furnished plants of Spruce and Scotch Fir, from 3 to 4½ feet high, and about 6 feet apart, mixing them well as possible so as to get the Scotch Fir taken out as the Spruce grows up. The Scotch Fir, not being a plant suited for undercover, is only used as a nurse for the Spruce, so that where the Spruce Fir can be had in sufficient quantity, the Scotch Fir should not be used. We also occasionally use the Austrian, Corsican, and Mountain Pines to form groups of cover in exposed parts of plantations, where neither the Spruce Fir nor any of the evergreen shrubs would succeed well, unless protected from the cutting winds which prevail at certain seasons of the year. These evergreen trees must be kept very thin, and allowed to remain green and branched to the ground. In the other spaces we plant small groups of Scotch Yew, Holly, and Portugal Laurel; and in the sheltered and shaded parts we plant clumps of evergreen Privet, Mahonia, common Laurel, Rhododendron, &c. Each variety is arranged in separate clumps, each containing from ten to a hundred plants and upwards, according to the situation and extent of the plantation. The distribution and arrangement of the different shrubs described in a former part of this paper is equally applicable to this, except that the groups and clumps in old plantations are made larger, and consequently more space will be allowed to intervene between the clumps, so as to admit the free circulation of light and air; but we would specially recommend the planting of low-growing trees or shrubs along the "rides" and margins of plantations, as being suitable for the preservation and protection of game. In planting these shrubs, the whole secret of success is in the thorough preparation of the ground. This may be done by making large pits, and adding some suitable soil when planting, or, what is much better, to trench the ground 18 inches deep where the group or clump is to be planted, and at the same time adding some suitable soil if it is required. The plants used should be a good size, well rooted, and of a bushy form; and we consider that to plant them close together and in groups and clumps, is a much speedier and surer way of securing cover for game than the general way of planting single plants about 6 feet apart. The advantages in favour of planting in groups or clumps are fourfold, viz:—1. Being planted close, they provide immediate protection and shelter to game. 2. Plants are healthier in appearance, and grow faster in groups or clumps, as they receive shelter from each other. 3. Groups or clumps of undercover are more ornamental and less tantalising to the sportsman than a mass of underwood without any arrangement. 4. The plants being planted close together in these groups or clumps, they serve as nurseries, from which plants may be taken to form undercover in other places; and, moreover, after the plants in these clumps have been thinned out and thoroughly established, an almost unlimited supply of plants may be obtained from some of the varieties, by layers. These layers are got by pegging the side branches to the ground till they are rooted, when they should be detached from the stem and allowed to remain for two years, after which they may be planted to form undercover elsewhere.

Where undercover is judiciously thinned and pegged down, no cutting over will be required for a number of years; but as most of the plants used for undercover have a tendency to get overdrawn and bare below, they will require to be cut down occasionally, even where they are under the best management. However, this cutting down should not be all done in one year, but a portion of it should be done every second or third year, not cutting it down straight-forward, but cutting down portions here and there, so as to keep up a regular supply of undercover all over the plantation. The quantity to be cut down at one time must be regulated by the size of the plantation, quantity of undercover, and other local circumstances.

III.—Plants Best Adapted for Undercover.

This to the planter of undercover is the most important part of our subject, as the success or failure depends in a great measure, on the proper selection of plants to suit the different soils and situations. We will, therefore, endeavour to give a descriptive list of the plants that are best adapted for the maintaining of undercover for game.

Norway Spruce (*Abies excelsa*) is admirably adapted for forming clumps of undercover in old plantations, or for planting as a nurse in mixed plantations. Being abundantly furnished with branches, if thinned in due time, and its branches allowed to remain green to the base, it forms good shelter and cover for game. On dry soils or exposed situations it invariably becomes stunted in appearance, and dies prematurely. Suitable for a great variety of soils, it thrives best in a moist loam and sheltered situation.

American Spruce (*A. nigra*), a dark-green variety, well suited for ornamental planting or game-covers, as it is impervious to the attacks of hares and rabbits; specially adapted for planting in poor soils and exposed situations; but like most of the Spruce tribe, it thrives best in a moist loam and sheltered situation.

Austrian Pine (*Pinus austriaca*), if planted and kept thin, so as to allow its branches to spread, is well adapted for cover in exposed situations, along with the Holly and Elder. Being naturally of a spreading habit, and a rapid grower, it is well worthy of being more extensively used; but as it is liable to be injured by hares and rabbits, it should be protected for a few years, where these animals are numerous. Plants that are intended for planting in old plantations should be of a bushy form, well rooted, and from 2½ to 4 feet high. The Austrian Pine is quite hardy, and thrives in a great variety of soils and exposures.

Corsican Pine (*P. laricio*).—This tree is not so well adapted by habit for cover as the Austrian Pine, its only recommendation being that it is not liable to be injured by hares or rabbits. It thrives in a great variety of soils, and is very much valued as a fast-growing hardy tree.

Mountain Pine (*P. montana*).—This is the best of all the Pines for forming undercover, as it is of a low spreading habit, very hardy, and thrives in a great variety of soils. Being of slow growth and dwarf habit, it cannot be recommended as a useful timber tree, and should only be planted so as to intermix with the other trees for the purpose of maintaining the undercover.

The Cluster Pine (*P. pinaster*).—This is the most suitable tree of the Fir tribe for "planting and maintaining cover for game" in exposed maritime districts, as its branches, when young, are naturally of a low spreading habit, and it seems to grow best when exposed to the influences of the sea breezes. It is suitable for a great variety of soils, but thrives best in a light, dry, sandy loam.

Azalea pontica, a slow-growing hardy shrub, well worthy of being more extensively cultivated, suitable for planting along the sheltered sides of plantations; is not liable to be injured by game, and besides flowering in summer, it has very ornamental foliage in autumn. It thrives best in rich peaty soil and sheltered situations, but will grow well in any light dry loam.

Box tree (*Buxus sempervirens*) is a slow-growing hardy shrub, specially adapted for planting in ornamental plantations, as it is not injured by hares or rabbits. It thrives well under the shade of large trees, and forms excellent cover for all sorts of game. Soil, light sandy loam, and situation sheltered.

Bramble (*Rubus fruticosus*) is found growing natural in a great many plantations, but in "game preserves," where it is not found, it is well worthy of being introduced, as, from its free-spreading growth, there are few deciduous plants better adapted for the protection of game. In young plantations it requires to be cut back every third or fourth year, to prevent it encroaching too near the young trees. It luxuriates on a great variety of soils and situations. The price is also very moderate.

Common Broom (*Cytisus scoparius*) is sometimes raised from seed for the purpose of forming "game-cover," but is generally found growing natural. It is one of the best plants for maintaining game-cover; for, although it should be partly destroyed by game in the winter season, it soon regains its former healthy appearance. It thrives best in light gravelly soils and exposed situations. To maintain good cover it should be pegged to the ground or cut down every fourth or fifth year.

Elder (*Sambucus nigra*) is principally adapted for planting in exposed situations as a nurse to the Holly and Pines. Its hardiness and rapid growth are its principal recommendations for game-cover. It will grow on almost any soil, but thrives best on deep loam moderately moist. To maintain efficient cover it requires to be cut down every second or third year. The Beech, Sycamore, and Birch can be grown as copsewood in the same situations.

Common Holly (*Ilex Aquifolium*) is very liable to be injured by hares and rabbits when first planted, and should, therefore, be protected for a few years till it is beyond their reach, and even some of the old plants will require to be protected with Spruce branches during a severe winter. It is the best evergreen shrub for planting in exposed situations, and it is also specially adapted for planting in groups on the outside of plantations. It thrives best on rich loam containing a quantity of vegetable matter. Being considered a shy grower at first, the plants should be well rooted before being removed to the plantation.

Common Laurel or Bay (*C. laurocerasus*).—This is one of the most free-growing evergreen shrubs, suitable for a great variety of soils, but grows best on a light loam with a dry bottom, and moderately sheltered; liable to be injured by hares and rabbits when first planted; but, if the plants are large and well-rooted, it soon grows beyond the reach of these animals. Being naturally of a low-spreading habit, with its branches generally reclining to the ground, and a very rapid grower, it is admirably adapted for the maintaining of "game-cover." After it is thoroughly established, it will require to be cut back or pegged down every sixth or seventh year; in fact, the more it is cut back or pegged down it seems to grow the faster.

It is best adapted for planting in clumps, and can be propagated by layers or cuttings.

Portugal Laurel (*C. lusitana*).—This, like the two former, is very liable to be injured by hares and rabbits when first planted; and should, therefore, be protected for a few years where these animals are numerous. Large plants of it are difficult to transplant, unless they are well rooted. Being of a compact habit it is well adapted for planting, either in groups or single specimens. It stands cutting well, and can therefore be kept to any size. Soil most suitable, rich loam, and situation moderately sheltered.—**Mahonia Aquifolium** is a low-growing hardy shrub, well adapted for forming clumps of undercover for pheasants; but, as it is generally destroyed by hares and rabbits, it cannot be recommended where these animals are numerous. It thrives well in any light loamy soil, if the situation is sheltered.

The Privet (*Ligustrum vulgare*) is a plant well adapted for forming clumps of undercover, and is one of the cheapest and easiest cultivated plants that can be used. It is a very rapid free grower, thrives on a great many varieties of soils, but requires a moderately-sheltered situation. It should be pegged to the ground or cut every sixth or seventh year. A great many young Privet plants are choked by Grass and other weeds after they are planted. They are also sometimes destroyed by rabbits. The Privet can be readily propagated by cuttings in any ordinary soil.

Rhododendron (*R. ponticum*) is the best of all evergreen shrubs for the "planting and maintaining of game-cover," as it will thrive on almost any description of soil, and is perfectly hardy, and in the most severe winters is never injured by hares or rabbits. It may be grown as single plants, but is specially adapted for planting in clumps. After the plants are thoroughly established in these clumps, they should be regularly pegged to the ground every year, as the more the Rhododendron is pegged down the faster it grows. When the clumps get too thick, the plants can be removed and planted elsewhere, as it stands transplanting well, even after it has grown to a large size. In fact, wherever permanent game-cover is required, the Rhododendron *ponticum* is quite indispensable, especially in old plantations. It thrives best in good peaty soil and sheltered situations.

Scotch Yew (*Taxus baccata*) is a very ornamental and useful evergreen shrub, well adapted for planting either as a single plant or in groups; thrives well under the shade of trees, but is of very slow growth for a few years after being planted. Its leaves are poisonous for cattle and sheep, yet it is often injured by hares and rabbits. It should, therefore, be protected for a few years till it is beyond their reach; thrives best in a sandy loam, and moderately sheltered situation.

Sea Buckthorn (*Hippophaë rhamnoides*) is specially adapted for planting in maritime districts, either as a nurse for the Pinaster or for the formation of "game-cover;" being of a straggling habit, it is well suited for this last-mentioned purpose, and is well worthy of being more extensively used, as it will luxuriate on the sea-coast, in exposed situations, and at an altitude where few other trees would grow; it thrives best in a deep sandy soil, but will grow in almost any ordinary soil; it can be readily propagated by layers or suckers.

Snowberry (*Symphoricarpos racemosus*).—This is a low, free-growing, deciduous shrub, well adapted for forming undercover, as it is seldom injured by game, even in severe winters. It luxuriates in any light free soil; and when once planted and established, it throws up numerous suckers from the roots, which soon spread over the ground. Its berries are very ornamental in the autumn and winter months.

A great many more plants may be used for undercover where there is little or no game to contend with; but as our subject is the "planting and maintaining of undercover for game, with an account of the plants best adapted for that purpose," the foregoing must be considered as selected according to the best of our knowledge. And, in conclusion, we beg to state that this paper may be considered more as a practical report than as a "finished essay," for we have recommended nothing to be done but what has been proved by experience to be beneficial to the "planting and maintaining of undercover for game."—*Transactions of the Scottish Arboricultural Society.*

The Sea Buckthorn (*Hippophaë rhamnoides*).—This native shrub, of which we seldom make effective use in the southern counties, is very striking in groups and clumps on the lawns in the northern part of Scotland, near the sea. The *Eucalyptus* at Dunrobin, as in various parts of Ireland and the Isle of Man, forms the most beautiful of all hedge plants.—*M.*

Durability of the Catalpa.—The *Germanstown Telegraph* says that timber of the Catalpa which has been in use many years in Delaware and other places, has proved equal to the Chestnut in durability when used as posts, and in other particulars it has been found of great value. Its rapidity of growth is also mentioned, the annual rings being found from a quarter to half an inch thick.

THE KITCHEN GARDEN.

BETROOT IN MARKET-GARDENS.

BET is a vegetable which is much appreciated in the London markets, and one which is very accommodating in regard to culture. The main sowing is made to succeed Wallflowers, Radishes, Spinach, or Cabbages, and it is often, also, grown on Asparagus ridges, between rows of fruit bushes, and between lines of Vegetable Marrows, and even when grown in the open field, it permits of being intercropped. It is also an accommodating root in winter, as it may either be left in the ground and thence marketed, or lifted and stored, as may be convenient to the grower, who may want the ground manured and trenched for Radishes or other spring crops. Dark crimson coloured Beets are those which are most esteemed by market-gardeners, most of whom grow their seeds saved from select plants having I think the Red Castelmandary and Dwarf Red for their parents. Carter's St. Osyth is a favourite Beet with many growers. Although Beet does best in an open situation, it is not in all cases that such a position can be assigned to it. The ground in which it is to be grown should not be manured beyond what it received for the previous crop, as freshly-manured ground causes the roots to fork, thus materially lessening their value. The soil should be deeply worked, however, in order to give the roots a downward tendency unchecked, and in this way fine clean medium-sized, entire roots are obtained. Such roots always fetch good prices. The first sowing is usually made where the plants are to remain, in lines about 15 inches apart, in the first week of May. Cleared ground is not always employed for this sowing, but, as a rule, the lines are drawn between rows of Cabbages or Lettuces, recently planted; after they germinate they are thinned a little with short hoes, and again when they form a few rough leaves they are thinned out to single plants. Many open the drills in the morning and sow the seeds in the afternoon, thus ensuring, they affirm, earlier germination than would otherwise be the case. Mr. Pocock raises good Beets after Wallflowers are cleared off between the rows of Gooseberry bushes. Mr. Dancer, of Fulham, and others, sow Beet seed on either side of their Asparagus ridges, but, thus circumstanced, they do not grow large. Transplanting Beets is only resorted to to fill up vacancies in the rows, as in the operation the main roots are often broken or otherwise so damaged, as to render it almost impossible for them to produce good roots. Some make a sowing in March in a sheltered piece of ground, for yielding an early supply. In harvesting a field of Beet where the roots have to be kept through the winter, the roots are carefully dug up, preserving the whole length of the root intact, and keeping 2 inches of the crown attached to it after the leaves are removed. They are first stored in pits, 4, 5, or 6 feet wide at the base, tapering about 3 feet in height. They are then covered with straw, over which a coating of soil is put to exclude frost. Leaving the roots in the ground is reckoned the best plan, as their proper flavour is thereby preserved better than when lifted and stored, but they are liable to be injured by frosts in January, or to be locked in the soil when it might be convenient to send them to market. Some of the darkest and finest shaped roots are kept for seed-bearing plants, and are planted in some out-of-the-way nook by themselves. F.

MARKET GARDEN TURNIPS.

SPRING TURNIPS are produced in quantities round London, but supplies for summer, autumn, and winter, are mostly furnished from a distance of ten or more miles from the metropolis. The Fulham Fields and Greenwich Thames Level are too high-rented to be devoted to late Turnip culture, but early outdoor and forced ones are raised in these districts in large quantities. The Early White Dutch is the variety commonly used for spring work. The seeds are, sometimes, sown on gentle hotbeds under frames, and sometimes on similar beds covered with litter, or hoops and mats. When grown under frames the routine is the same as that practised with most kinds of plants raised from seeds. The method of growing them in hotbeds without frames is as follows:—Pits are cast out 18 inches deep, 6 feet wide, and of any length, and firmly filled

with manure; over this a coating of soil is placed and rolled or beaten solidly with the back of a spade; the seed is then sown, slightly covered, and finished off by rolling again; hoops and mats are then fixed over the beds, and, in the event of hard frosty weather setting in, some strawy litter is added to the covering. If at all practicable, the mats are partly unfastened and let down every day so as to admit light to the young plants; and, as soon as it can be done with safety, they are removed from the beds altogether, but are left erect around their sides in order to ward off winds. Turnips are sometimes grown without the aid of either frames or hoops and mats, on hotbeds like those just described, and in this way I have seen excellent Turnips produced. When the seed is sown the beds are merely protected by means of a layer of litter, which is put on and off as in the case of Radishes. The earliest sowing is made in the last fortnight of January or early in February, and main sowings of the Early White Dutch, or White Stone, but generally the former are made broadcast on a field about the end of February, or in March, to be succeeded by another sowing made in April. After the plants come up they are thinned, and the surface-soil is at the same time loosened by means of small hoes. The largest roots are first drawn for market; thus the plants get thinned, and those that remain have more space for development. Some use the space between the lines of frames for growing Turnips; and well it answers for that purpose, as, owing to the soil being under the general level, it keeps comparatively moist, and the belts of frames protect them considerably from inclement weather. Spring Turnips are generally got off the ground in good time, to permit of its being cropped with French Beans, Summer Cabbage, Spinach, or Celery. Turnips for autumn use, and also the winter ones, consist chiefly of the White Stone, which is a beautiful white-rooted sort, which cultivators generally sow on ground just cleared of Peas, and send them to market in winter. In February, Turnip Greens are usually a valuable part of the crop. W.

A Normandy Vegetable Market.—One has to push through throngs of basket-women to reach the fruit and vegetable stalls. The clatter, the laughter, the gesticulation and harangues of a keen-faced dark-eyed man, in a blouse, who is selling an immense pile of Melons by auction—all the merry sounds so indescribably French, are bewildering, but they seem to fill the place with sunny mirth. It is a bright morning, too, after the rain, and the sun seemingly revels among the Potirons and Citronelles lying about in front of the stalls, some of them with a slice cut out, glowing with the delicate golden tint within. Beside the stall is a heap of tin and wooden measures, and on these lies an open sack of Cornichons, another of rosy Onions; in front is a basket of large white Radishes, a heap of orange Carrots, glowing against their feathery foliage, and a bunch of silver-skinned Leeks; Cabbages, not crammed out of sight in a basket, but arranged on the stall so as to show their exquisitely-veined leaves to the best advantage; a few creamy Cauliflowers, placed temptingly beside a pile of scarlet Tomatoes; and, raised higher, so as to be more under the shadow of the canvas overhead, are Plums and Peaches and Grapes. The Pears are not unpacked yet, but they lie brown and tempting in the months of their open baskets. There does not seem any attempt at effect, and yet everything is placed in happy harmonious contrast; the Turnips and Carrots have been carefully washed; everything is at its brightest and best; no one seems to have a care or a trouble on market day. Our friend, the Melon auctioneer, is having a fierce battle with a woman as sharp-looking as himself. He has been brandishing a clasp-knife so close to his own thin nose that the effect has been alarming; and now, as his customer flattens her nose on the Melon, in the endeavour to test its soundness, he snatches at the fruit and plunges the knife into it, as if he were stabbing an enemy; he hands her the slice, but she shakes her head. "Gathered green," she says, with a smile. She turns away, and our friend stamps, and, catching sight of us, holds out the Melon. "Gathered green!—ma foi—smell it," he screams; "taste, and then see if it is not the cheapest of Cantaloups, only one franc-and-a-half for the best fruit in the market."—K. S. MACQUOID.

Fairy Rings at Rothamsted.—It is rather remarkable, considering how largely Fungi abound in nitrogen and require ammonia as manure, that in my Grass experiments the only places where the Fairy Rings abound are upon those spaces in which mineral manures alone have been used, and where no manure containing ammonia or nitric acid has been applied for twenty years. Where the two latter substances have been used, either with or without mineral, I am unable to find any of the Fungus tribe.—J. B. LAWES, Rothamsted.

CHANGE OF CLIMATE IN SCOTLAND.

MR. M'NAB some time ago (see p. 238, Vol. V.) made some remarks on this subject, the drift of which was to the effect that, as compared with forty or fifty years ago, a perceptible change to a lower summer temperature has taken place. This opinion is based, so far as appears, entirely on the growth, or defective growth rather, of various of the less hardy trees and shrubby plants, several of which are enumerated—such as the Myrtle, the Acacia, the Almond tree, the Hydrangea, the Arbutus, and others. The comparatively unsatisfactory growth of the Larch now-a-days is also adduced as a proof of diminution of temperature. Indeed, the general belief is that our summers now, in point of temperature, are not what they were.* Mr. Buchan, secretary of the Meteorological Society of Scotland, however, is of opinion that little or no change has taken place. The current notions about a change in climate includes not only a lessened summer heat, but still more—a change in the direction of a higher temperature, or less severity in winter. In a word, that the summers are cooler and the winters milder than, say, fifty or sixty years ago. What, however—and it is, perhaps, the crucial point—do the meteorologists say? How far do tabulated results strengthen the case for a change of climate? Unfortunately, there is for the early period indicated by Mr. M'Nab no official data at all. The Scottish Society has only been in existence since 1855, and its labours do not therefore include a period of much more than fifteen years. Observations of a reliable kind, and for longer periods, are extant, but even they do not extend backwards far enough. We have the results then, for fifteen and about thirty years respectively, but there is nothing of an earlier date to compare them with. It is very interesting to notice, by the way, that the difference between the mean temperature of these two periods is infinitesimally small. Edinburgh, for example, in the tables furnished by Mr. Buchan, shows in the one table 45°·9, in the other 47°·1; Arbroath, 46°·5, and 47°·0 respectively. As an example of the influences of the western sea in equalising the temperature on the west coast, the case of Bute may be added (although not from the same tables), which shows nearly three degrees less than Edinburgh, and about a degree and a half less summer heat. Here the case may be supposed to break down for want of evidence. Lately, however, in going over some old volumes in the *Scots Magazine*, it was observed, that for a considerable number of years a table of daily thermometric observations in the vicinity of Edinburgh was printed. And it was thought that the data obtainable from these records might, in the absence of official returns, be available for the purposes of comparison. The mean temperature deducible from the figures was therefore worked out for the three coldest and warmest months for a period of thirteen years at the beginning of the century, and the results are presented below, along with a table of the mean temperature of Edinburgh, for the same number of recent years, extracted from the *Journal of the Meteorological Society*. The question, however, immediately arises, how nearly these earlier observations correspond, as to the time of day at which they were made, and so on, with those on which the Society's tables are based. The latter indicate the mean of the maximum and minimum temperature of each day of twenty-four hours. The observations in the *Magazine*, on the other hand, must have been made without the aid of the more exact modern instruments, for as yet registering thermometers, although invented, were imperfect and not in general use. Hence, instead of the daily maxima and minima of the recent tables, we have a daily observation "in the morning before sunrise," and again "at noon." These, however, although failing perhaps to give the very highest and lowest point, will probably indicate a pretty close approximation to the true mean temperature, inasmuch as the times of examination may be considered about equally distant from the extremes. The figures in the first column are, as has been said, based on an induction of thirteen years, and include the year 1801, and from 1804 to 1815 inclusive. The intermediate years were not accessible.

	Mean temperature for thirteen years from 1801, &c.	Mean temperature for thirteen years from 1857 to 1869.
WARM MONTHS.		
June	57°·6	55°·6
July	61°·0	58°·3
August	59°·9	57°·7
Average of three warm months	59°·5	57°·1
COLD MONTHS.		
December	37°·9	39°·8
January	36°·8	36°·3
February	39°·0	39°·1
Average of three cold months	37°·9	38°·4

These comparative statistics, so far as they are reliable, do certainly afford countenance to Mr. M'Nab's contention for a diminished summer

* The month of July just past is, probably, an exception to this remark. This paper, it may be mentioned, was written some time since.

beat. There is a difference, it will be observed, of almost $2\frac{1}{2}$ degrees in the summer months, which is a tangible diminution, equivalent to the difference of mean annual temperature at Edinburgh and Great Malvern. In the winter months, again, the heightened temperature of the latter period shows itself almost entirely in December, the variation in which month in the two tables is over 2 degrees—a result entirely according with the general experience of many recent years. A few months ago Mr. McNab laid on the table of the Botanical Society an extraordinary collection of plants and flowers gathered in the Botanic Gardens on New Year's Day, and come to some measure of maturity long before their time. May not the fact, by the way, of these oft-recurring mild Decembers account somewhat for the deficiency of vigour later in the year, which is the foundation of his argument. The unseasonably high temperature hastens unduly vegetation of all kinds, which, nipped by the frosts of the spring months, does little more good for the season.—*Scotsman*.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

Indoor Fruit Department.

VINES.—Lady Downes, Black Alicante, Barbarossa, Muscats, Syrians, and other Black and White late kinds, should now be on the eve of maturity; where the borders were liberally watered until the fruit began to colour, no more water will be needed at the root, otherwise, and where the Grapes have to hang until late in the season, or into next year, a good watering should be given at once to prevent ultimate shrivelling. The condition of the roots has as much to do with the perfect keeping of Grapes as a genial state of the atmosphere; where Grapes are not yet ripe, keep the temperature during the day from 85° to 90° with sun heat; shut up early in the afternoon, and do not let the temperature fall below 65° at night. Such as are ripe will do with 10° less by day and night, and the inside of the house in which they are grown should be kept dry, and should have a little air at top and bottom left on at all times; half an inch is sufficient, more dissipates the heat, and then cold air is admitted in voluminous currents. Pinch or cut away all growths which may have been formed beyond where the shoot was originally stopped, to allow a free circulation of bracing air about the wood and bunches. Do not use any of the thick-skinned sorts where thin-skinned ones, such as Hamburgs, Golden Champions, Muscadines, &c., are still to be had. The latter will not keep well if wet weather sets in, while the former will improve in flavour by hanging a considerable time after they are ripe. Clip out all decayed berries as soon as visible, for if even one is left, it soon affects and destroys numbers of others. Vines that have produced the midsummer supply will now be clear of their crops; their foliage should, therefore, be syringed thoroughly to dislodge red spider, &c., in order that the leaves may remain fresh to assist in ripening the wood. Now is a good time to put an addition to outside borders; where these are not fully made up, 2 feet of new soil should be added to them; the best fibry loam that can be got should be selected for that purpose. Numbers of different ingredients are not necessary at any time, but often hurtful. Add one bushel of ground bones to every two cart-loads of loam, and mix the whole well up together. In applying it, gently fork down the old soil, until roots are observed; then apply the new soil, and they will at once work into it, and be prepared for vigorous action when required next year. Pot-Vines will be fast ripening their wood. Do not give so much water at the root. Never let them get over dry, or they will cast their foliage prematurely, and not thoroughly ripen their wood. Those intended to furnish an early supply, and which have been grown in a high temperature, should be removed into a cool house, or outside altogether, that they may have the more perfect repose. Do not set them at the back of a north wall, or any such place; but let them be fully exposed to the sun, and a little sheltered from strong and cold winds at night.—*J. Muir, Clonsford*.

Hardy Fruit.

Seldom or never have the roots of fruit trees been so dry as this season; and to this circumstance may be attributed, chiefly, the premature dropping of so many fruits. It is, however, not yet too late to water late Plums, Pears, Apples, and Peaches, and enough should be given to soak their root-runs through. Hardly will this have been done, when the fruits will be seen to enlarge in size and to grow in luscious juiciness. The fact is, in dry situations the fruits have been half-starved and parched up. They are waiting for the coming of autumnal rains to enable them to finish creditably; but, hitherto, they have waited in vain. Sewage will now do more good than clear water, provided the fruit is very late; but it is safest not

to give sewage within a fortnight of maturity. It is good practice, in such seasons as the present, to water the roots of the trees thoroughly, even after the fruit is gathered. Excessive dryness at the roots may seem to hasten maturity; but, if it does so, at all, it is brought about prematurely, and weed prematurely ripened can hardly yield good crops. Continue also to wash the trees on walls overhead daily with the garden engine; a clean top and sufficient moisture at the root are two of the best means of furnishing and finishing fruit-bearing wood. Autumnal waterings are likewise useful in destroying root fungi, which, if unchecked, work sad havoc among wall and other trees. Protect late Plums, Cherries, Pears, and Peaches, with tiffany, hexagon, or other wasp or fly-proof matting; also, trap these pests in bottles baited with sugar and water, and beer. Watch fruit that is ripening and gather it daily. Fruit is higher flavoured gathered a day or two before it is ripe, than when allowed to hang on the tree until it drops.—*D. T. Fish*.

The Flower Garden and Pleasure Grounds.

In favoured localities flower gardens will by this time be at their best; but in many others, perfection, as regards floral beauty, will hardly be realised this season. This, however, must not be allowed to interfere with such attentions as must necessarily be paid to routine operations, such as mowing, sweeping, removing dead and decaying flowers and leaves from the beds and borders, and by this means they will be rendered attractive and enjoyable for at least a month or more to come. The mixed or herbaceous border should now have careful attention, as Phloxes, Pentstemons, and many other late autumnal flowers, will now be in full beauty, and should not be in any degree marred or disfigured by being associated with the decaying flowers and foliage of other occupants of the border, nor should such plants be by any means cut down prematurely, or in an unripened condition; but, at the same time, all dead and decaying matter may be removed with advantage to them as well as to the general appearance of the garden. As regards annual plants, they should be at once removed as soon as their beauty is over, unless in cases where seed may be required, and this should be carefully picked as it becomes ripe. A border of herbaceous and Alpine plants and bulbs, whether situated upon the margins or belts of flowering and evergreen shrubs or otherwise, should be so arranged as to have the flowers peculiar to the different seasons so distributed throughout the entire length and breadth of the border that no portion of it will, at any season of the year, be entirely destitute of flowering plants; and care should also be taken to properly graduate the various species as regards their bulk and height, so that dwarf growing plants may not find themselves partially hid or overshadowed by taller growing sorts. Beds or clumps of double-flowered Zinnias are now in fine condition and are most valuable as autumnal flowering plants, and possess the power of resisting drought to a very considerable extent, especially if a deep, rich, and well-manned soil has been selected for them, and such encouragement they well deserve. They should be sown under glass, about the end of March or early in April, and should be planted out about the end of May. They may be planted tolerably close together, say about 6 or 8 inches apart, and all inferior sorts should be extracted from the bed or clump as soon as they show flower, and the space they occupied will soon be taken possession of by the remaining plants. Go carefully over the beds now and select a few of the very finest and most distinct blooms as seed-bearers, and mark them by securing to them pieces of coloured worsted or other material, and pick them as soon as they are ripe; and, by this means, the strain will be continually improved, while the reverse will sure to be the case if the seeds are gathered indiscriminately. Let Chrysanthemums, German and other Asters, as well as all other late-flowering plants, be carefully staked to prevent them being blown down or injured by high winds. Order, or get in readiness, the various bulbs which will soon be required for furnishing the flower-beds for spring. The cuttings of such plants as the Verbena, Petunia, Coleus, and Alternanthera, which may have been struck in close frames or pits, will now, in most instances, be well rooted, and the store pots or pans containing them should be placed on cinder ashes in the open air, fully exposed to the sun for some time, or as long as it can be done with safety, and this will have the effect of rendering them robust and hardy, and it is of the greatest importance to have them in this condition before the approach of winter; only care must be taken not to expose them too long.—*P. GRIEVE, Cult. ford, Bury St. Edmunds*.

Roses.

As autumnal Roses will now be coming into flower, all who need a further supply of them will do well to visit some of our great Rose nurseries, and select, while they can, such sorts as please them best, some being fond of a full-cupped Rose, others of large flat kinds, and a few even like loose-petalled Roses. In selecting new varieties for planting out, it is best to buy the strongest and best plants, for

great disappointment is often caused through buying a small plant which, when planted out, looks very small; and, if a weak grower, sometimes dwindles away and dies. I always have the smallest plants potted and put into a cold pit or plunged among leaves in some warm corner out of doors, and plant out in March, if I cannot get plants strong enough to plant in November. The following are a few varieties which I noticed this week in full bloom, viz., *Devoniensis*, *Belle Lyonnaise*, *Gloire de Dijon*, *Safrano*, *Maréchal Niel*, *Celine Forestier*, *Lamarque*, *Ophirie*, *Souvenir de Malmaison*, *Rev. H. Doubrain*, *Louise Odier*, *Anna Alexiëff*, *Baronne Prévost*, *Beauty of Waltham*, *Boule de Neige*, *Charles Margottin*, *Jules Margottin*, *Duke of Edinburgh*, *Elizabeth Vigeron*, *Princess Mary of Cambridge*, *Madame Julie Duran*, *Auguste Mie*, *Prince Camille de Rohan*, and *Princess Louise Victoria*. At this time of the year we have little to do except to remove suckers and weeds and enjoy our second harvest of Roses.—H. G.

Indoor Plant Department.

In stoves reduce the shading to a minimum; but do not remove it altogether, for sometimes we get extremely bright weather even up to the end of this month, by which injury is often done through scorching, especially as it is necessary now to use much less moisture in the atmosphere, as well as to admit more air; both of which render the foliage more liable to scorch. The object of the cultivator in this matter ought to be to just shade sufficiently to prevent injury, but no more, not even for a single hour. This is a point the importance of which should be urged, as so much depends upon the manner in which stove-plants are treated in this respect, during this and the following month, with a view to their flowering freely the ensuing season. From *Allamandas*, *Clerodendrons*, and *Bougainvilleas*, gradually withhold water, allowing them to flag for a day or so before giving any, and then only give it in reduced quantities; by continuing this treatment the soil in the pots will gradually get to that (at this time of the year) necessary condition as to moisture, that it contains just sufficient moisture to maintain the roots in health, without inducing any disposition in the plants to form more wood. *Stephanotis* requires to be kept after this time comparatively dry; but, unlike the preceding plants, being evergreen, it will not answer if the soil gets too dry, as the leaves would suffer and drop off. *Dipladenias* should also be kept drier than when it is desirable to encourage active growth, yet not so dry even as the *Stephanotis*. *Ixoras*, again, must be kept at this season drier than when their growth is most active, but must never be allowed to get too dry, or they will suffer to an extent that will take the best part of a season to recover them. Nothing adds more to the good appearance of the stove than a few suspended baskets of such things as *Hoya bella* or the different varieties of *Æschynanthus*; of the latter, *Æ. splendens* and *Æ. Boschianns* are most desirable plants, of graceful drooping habit, brilliant and free-flowering; growing freely in an equal mixture of loam and peat, with sufficient sand to ensure porosity. Reduce the atmospheric moisture of the Fern house, and also the roof-shading, but this only in a comparative degree; Ferns having no wood to mature and solidify like flowering plants, neither require, nor will they bear this additional sunlight, and drier root treatment being carried so far as in the case of flowering plants, without suffering seriously. What they do require at this season is simply to carry this treatment so far as to check the disposition to make growth and rest the plants, so as to get them in that condition that they will move with vigour when the season of active growth comes round. The late-blooming *Azaleas* will now be setting their flower buds, and should be no more shaded. The syringe should also be withheld, simply throwing a moderate amount of water about the floors and paths, at, say, four o'clock, when the house should be closed, allowing the temperature to rise by sun-heat, which is at once the most genial to the plants and the most economical. Continue this practice until the flower-buds are up as large as small *Camellia* buds. If their inveterate enemy, the thrips, makes its appearance, give it no quarter; any delay in this matter entails a serious after expenditure of labour. Get all the plants, large and small, tied before they have quite completed their growth and the wood becomes hardened thoroughly, as after that they are too stiff to regain the natural position a ter tying. Hard-wooded plants will still be out-of-doors to harden and mature their seasons's growth. See that they are well attended to with water, and syringe in the evenings all such as are not liable in the winter to the attacks of mildew. On the other hand, see that they do not get their soil too much drenched by heavy rains, otherwise irreparable injury will follow. Heaths should all be now fully exposed in the open air, except such as evince by the absence of free growth, that they are weak at the roots. If any such exist, it is better to keep them under cover, giving all the air possible night and day, and be careful not to let them get too wet at the roots. Heaths that become somewhat stagnant at the roots in the way

described may sometimes be brought round by careful treatment of the soil.

Kitchen Garden.

Mushroom beds should be made up in September for winter bearing. In most private gardens Mushrooms are usually grown for winter supply in houses or sheds built for the purpose, generally at the back of the forcing-houses, and such houses are exceedingly useful for forcing many other things besides Mushrooms. Rhubarb, Seakale, Chicory, &c., may be quickly and cleanly forced in a Mushroom-house without the labour and litter which usually accompany the forcing of these plants in the open air. Although I do not consider any private garden complete without a Mushroom-house, taking into consideration the many uses to which it can be put, I do not, of course, consider such a structure absolutely necessary for the successful culture of Mushrooms alone at any period of the year. With respect to Mushroom culture, however, whether it is carried on in sheds, cellars, or in the open air, it is necessary that a steady heat of 75° or 80° should be maintained in the beds, during the time when the spawn is running, but which may be allowed to fall to 60° or even 55° during the growth of the Mushrooms. In Mushroom houses properly constructed and heated there will be no difficulty in maintaining the requisite temperature, but open air beds in winter, sometimes, involve a good deal of trouble in covering to keep off heavy rains and maintain the necessary amount of heat in the beds, without which the spawn would perish. All this is, however, a question of skill and care on the part of the cultivator; and let me add also a question of means in the shape of plenty of fresh stable dung, to make the beds, and for coverings and linings to them afterwards, in bad weather. Years ago, it was considered necessary to shake out, as far as possible, all particles of straw, and to use only the droppings in the construction of the beds—a practice now proved by many cultivators to be unnecessary. I have seen better crops of Mushrooms grown with the dung fresh as it came from the stables, with only the longest and driest straw shaken from it, than when considerable pains have been taken to secure only the droppings, and a good deal of time lost in waiting for and watching its fermentation before it was considered safe to make up the bed. Whenever the dung is used fresh, however, or comparatively so, it is necessary that a certain proportion of fresh loamy soil, varying from a sixth to a tenth of its bulk, should be thoroughly mixed with it; and the beds should be built up in layers, and each layer well beaten or trodden down; and the more thoroughly this is done the less danger there will be from over-heating, and the longer and better will the beds bear. I am of opinion that, in many cases, where several weeks are occupied in fermenting the dung before it is used, a good deal of the nitrogen which it contains is drawn out of it in the process, and that the chances of a good crop are thereby rendered more uncertain. This is a good time to sow a few seeds of Brussels Sprouts and of the various kinds of Broccoli for next year's planting. Sow thinly, as the plants will remain in the seed-beds till the end of February, when they may be pricked out. I am convinced that one of the chief causes of such things as Broccoli suffering so much during severe winters is late sowing, and, as a consequence, late planting and late autumn growth, which must be soft and watery; and, therefore, a prey to the first severe frost. In autumn, before the earth has parted with its summer heat, seeds of all kinds vegetate freely; it is best to sow in a dry south border. Red Cabbage should also be sown now for next year's pickling; and, if desirable, a few seeds of other kinds of Cabbages may be sown to succeed the spring Cabbage. Spring-sown Onions should be pulled up and harvested previous to storing.—E. HOBDAV.

Cottagers' Gardens.

Advantage should now be taken of spare hours to thoroughly eradicate all weeds before the dark dull days of early winter have arrived. The most effectual remedy is to hoe the ground deeply several times in succession at short intervals, so as to bring the seeds to the surface, an operation which will also be beneficial to growing crops. Onions will now require harvesting, and when thoroughly dry should be stored in an open airy situation. The best crop to succeed Onions is Cabbage; as soon, therefore, as the ground is cleared, wheel on to it a good dressing of well-rotted manure, of which too much can scarcely be given, as Cabbages grown as they should be on highly manured ground, are very different from the stringy produce of poor land. Early Apples will require gathering, but on no account should valuable late keeping sorts be gathered before they come easily off the tree. In flower borders a few seeds of such pretty spring flowering plants as *Saponaria*, *Nemophylla*, *Silene*, &c., may be sown, and cuttings of *Geraniums* should be at once inserted either in boxes or pots to be protected through the winter. Collect seeds from annuals and such other plants as are usually increased in that manner.—J. G.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL SOCIETY.

SEPTEMBER 2ND.

Dahlias, which formed the chief feature of this meeting, were unusually good, although somewhat limited as to numbers; and one or two of the stands of Gladioli shown were also above average excellence. There were one or two good collections of Apples and Pears; and vegetables, more especially Potatoes, were of splendid quality. Messrs. James Carter & Co. sent a good collection of culinary herbs and curled Kales; while Messrs. Veitch & Sons contributed a fine miscellaneous group of Orchids, Solanums, Ruscus, and other decorative plants, including specimens of the extremely curious orange-flowered *Blumenbachia* (*Cajophora*) *coronata*. It may be remarked that, as the generic name *Blumenbachia* had been previously applied to a section of the genus *Sorghum*, *Cajophora*, Hooker's name ought, therefore, to have preference, so as to avoid that confusion which is becoming intolerable to cultivators as well as to botanists.

Dahlias.—Of these, Mr. Keynes, of Salisbury, had a splendid stand of thirty-six varieties, among which were John McPherson, fine purple; Mrs. Eckford, bluish white; Pauline, orange-red; Willie Eckford, rich crimson, purple centre; and Monarch, a deep velvety-purple; Picotee is a fine flower of a golden-yellow colour, with a reddish margin to the florets; Memorial, bright rosy-purple; Yellow Boy is one of the best of the golden-flowered section; and Flora Wyatt is a good red. Mr. Charles Turner staged a nice lot of well formed flowers, the following being especially worthy of note, Prince Arthur and Julia Davies, both fine yellows; James Service, crimson-maroon; King of Primroses, straw yellow; Mrs. Henshaw, white; W. P. Laird, lilac striped with purple; Princess, white; and Earl Radnor, crimson-purple.

Gladioli.—The season for these is, of course, on the wane, but several good stands were shown by Messrs. Kelway & Sons, and Lord Hawke, staged twelve excellent spikes in the amateur's class. Among the varieties staged by the different exhibitors, we noted the following as worthy of more than a passing notice:—Norma, white, purple stripe; Sparkler, a fine vivid scarlet; Mr. Tucker, white, rosy-purple stripe. Mr. J. Douglas, a well-known amateur grower of this noble flower, had a fine stand, a large proportion of them being seedlings of his own raising, and although the spikes were scarcely so large as those of Messrs. Kelway, they were especially remarkable for richness of colouring. One of the best in Mr. Douglas's lot was Horace Vernet, a glowing fiery scarlet, the colour being intensified by a pure white stripe.

Asters.—These are amongst the finest and most generally useful of all hardy annuals, and every year seems to improve them either in perfection of flower or habit. Messrs. Veitch & Sons staged a fine group of "Boltze's Dwarf Bonquet," a fine dwarf profuse flowering strain, well adapted for pot culture, the flowers being compact and of the most brilliant shades of rose, lilac, purple, and carmine. Messrs. Carter & Co. staged fine cut blooms of *Anemone*-flowered kinds, these being nearly as beautiful as the show varieties. The only collection of Asters in pots for competition came from Mr. R. Dean, Ealing, the plants being well bloomed, but too large and coarse in habit as pot plants. Mr. Lakin, of Chipping Norton, staged an excellent group of cut blooms in the class for French varieties; these flowers were of good size and well coloured, the leading shades being blue, purple, rose, lilac, and white. Mr. T. Benham staged an equally fine collection of Quilled or German Asters, which are as easily grown as the others, and quite different in form, thus affording an agreeable variety. Mr. Lakin also exhibited cut flowers of Zinnias, the colours being remarkably rich and brilliant, the prevailing shades are orange, yellow, crimson, and purple.

Miscellaneous.—Mr. W. Ball staged a well-grown group of *Croton* majesticum, the foliage being remarkably well coloured. As shown, it promises to be one of the finest of all for exhibition purposes. Mr. Barr sent a splendid group of Lilies (cut spikes), principally of the auratum, tigrinum, and speciosum types, some of the forms being very fine. A spike of *L. tigrinum* splendens was the finest hitherto exhibited—even better than the excellent representation recently given to the *Flora des Serres* (t. 803). Cut flowers of a fine double Sunflower, named *Helianthus fistulosus*, came from Mr. R. Tanton; but it proved to be the *H. californicus* insignis of Otto, and, in all probability, is only a double form of *H. annuus*. It is a fine showy plant, well worth culture. Messrs. E. G. Henderson & Sons sent a group of decorative plants consisting of white, rosy, and yellow-flowered *Neriums* and new *Sonchilias*, to which we alluded at the time when certificates were awarded them, and also two or three rare *Selaginellas* and other plants. Mr. Parker, of Tooting, sent fruiting plants of the curious *Epigynum leucobotrys*, having bright green leaves and clusters of berry-like fruit of ivory whiteness, marked with black in a very distinct and striking manner.

Fruit and Vegetables.—These formed an interesting addition to the show. Early dessert Apples were fairly represented, the fruit being of excellent quality and flavour. Mrs. Benham had a nice dish of fruit named Duchess, and Mr. T. Benham had a handsome dish of Red Astrachan, fresh as when gathered, and covered with a delicate bloom. This is one of the prettiest of all dessert Apples, and is worth culture for its distinct and novel colour, and fine appearance on the table. Pears were in most cases excellent, and like the Apples, were partially judged by flavour, the prizes going in nearly every case to Williams's Bon Chrétien, undoubtedly one of the most delicious of all Pears at this season. Those sent by Mr. B. Porter, and Mr. Moorman, were very fine. Mr. Dancer sent fine specimens of Souvenir du Congrès Pear, which in colour and flavour somewhat resembles the last-named, but the fruit is larger, and curiously

flattened at the apex. It is said to ripen well on the tree, whereas Williams's Bon Chrétien requires to be gathered before it is ripe, in order to fully mature its delicate flavour. Mr. Groom, of Henham Hall Gardens, sent another specimen of his new African Melon, which the committee thought most excellent in point of flavour, but considered it to be too large. We can only repeat our previous statement, that it is the finest-flavoured Melon we have hitherto tasted, as well as one of the noblest in appearance. Fine Cucumbers came from Mr. Bloxham, but were not considered any improvement on existing kinds. Mr. Bennet, of Hatfield, sent specimens of Lord Palmerston Peach, and excellent fruit of Keye's Early Prolific Tomatoes. Mr. G. Pragnell sent a fine basket, well filled with various vegetables, usually known as Salads. These consisted of Mustard, Cress, Endive, Lettuce, Chickory, Cucumbers (Rollison's Telegraph, true), Water-Cress, and Radishes, the whole being neatly arranged. The same grower also sent remarkably fine specimens of the Giant Rocca Onion, some of which were nearly 8 inches in diameter. The collections of vegetables were of excellent quality, especially those sent by the last-named exhibitor, who had White Spanish Onions, very fine; Potatoes, Brussels Sprouts, Peas, Artichokes, Carrots, and French Beans. Mr. Bloxham had fine specimens of Smith's Frame Cucumber, which is a fine, fresh-looking variety, said to be more prolific than the Duke of Edinburgh, which it somewhat resembles. The Leeks in this collection were of especially fine quality. Mr. G. T. Miles had a fine group of produce, but slightly inferior to the last.

Potatoes.—There was an excellent display of fine tubers from some of the principal nurserymen and growers, and it is surprising to see the improvement effected during the last few years in producing smooth, fine skinned, shallow eyed varieties, retaining a fine flour-like appearance when cooked, the best quality in a good Potato. The best kinds now in cultivation were exhibited in excellent condition as a rule, although in one or two cases the disease was but too evident. The twenty dishes sent by Mr. R. Dean were really excellent in every way, and deservedly obtained the premier award. Mr. Ross, Mr. G. T. Miles, Messrs. Carter & Co., Mr. Pragnell, and Mr. Osman, also had good collections. Among the best sorts shown were the following, Model, Early Coldstream, Early Market (one of the very best), Bountiful, Fillbasket, Early Goodrich, Red Emperor, Snowflake, Myatt's Prolific, Mona's Pride, Dalmahey, Red Regent, and Oxford Kidney.

First-class Certificates were awarded to the following new plants:—*Nerium* New Red (E. G. Henderson).—A fine free-flowering single form of the old *N. splendens*, compact in habit, and well adapted for a greenhouse decorative plant.

Dahlia John McPherson (Keynes).—This is a finely-formed flower, of good size and of a rich violet-purple colour. It is a good exhibition flower.

Dahlia Countess of Penbrooke (Keynes).—A large finely-formed flower of a delicate yellow colour, the central florets being tipped with violet-purple.

Odonoglossum maxillare (Shields).—A very striking species, the flowers being of pearly whiteness, with the exception of a soft yellow stain on the crest of the lip, and a large velvety blotch of dark brown at the base of each segment. It is dwarf in habit, and a decided acquisition to a beautiful group.

Recoelodes guineensis (Bull).—A distinct and handsome terrestrial Orchid, bearing tall spikes of showy flowers. The sepals and petals are brownish-purple, the chief beauty of the flower being in its large flat rosy-purple or lilac coloured lip. It is of easy culture and worth a place in every collection.

Solanum Quinque (Veitch).—A strikingly handsome plant of the large-leaved section. The leaves are fully 2 feet in length and nearly as broad, of a vivid velvety green with conspicuous hairy purple-tinted veins. As a sub-tropical or conservatory plant it will be very valuable.

Hybrid Begonia Model (Veitch).—This is a strong-growing profuse-blooming plant, well worth culture either as a decorative pot plant or for cut flowers. The individual flowers are very large, of a vivid rose colour, borne in axillary cluster on long pedicels.

Selaginella lepidophylla (E. G. Henderson).—This plant is sometimes known as the "Re-urrection plant," and is well worth culture as a decorative plant. Its fronds are flat and of a vivid green, freely produced in a rosulate manner.

Gladiolus Duchess of Edinburgh (Kelway).—A nice addition to new varieties, bearing a fine spike of large rosy flowers, having a white purple-striped centre.

Gladiolus James Kelway (Kelway).—This is a glowing scarlet variety with a white stripe, and an excellent kind for exhibition purposes.

Botanical Certificates were awarded to the following:—

Drosera glanduligera (Bul).—In habit this interesting plant closely resembles a large-growing form of *D. rotundifolia*. It is a native of Australia, and is undoubtedly the same as *D. Whitakerii*, figured in the current number of the *Botanical Magazine*. The flowers are solitary, as large as a silver sixpence, and of a pure white colour. Neat in habit and a profuse flowerer, it deserves a place in every collection.

Drosera Menziesii (Bull).—This is an extremely slender-growing caulescent species, from Australia, good specimens being fully a foot high. It merits a place in gardens devoted to vegetable curiosities.

Whiskey from Moss.—The Department of Agriculture at Washington has received a communication from Mr. C. C. Andrews, representative of the United States at Stockholm, representing the production of whiskey, in Sweden, from Lichen or Reindeer Moss. The manufacture was begun in 1863, by a process invented by a Swedish chemist, Professor Stenberg. For six years the quantities of Moss used, and of whiskey—50 per cent. alcohol—produced, were as follows:—

Year.	Moss, lbs.	Whiskey, Imp. Gal.	Year.	Moss, lbs.	Whiskey, Imp. Gal.
1868	3,315,928	163,008	1871	1,720,141	84,672
1869	6,001,470	294,012	1872	2,149,051	105,498
1870	3,565,384	175,104	1873	704,793	34,560

Mr. Andrews states that the falling off in production is owing partly to the abundance of other materials for whiskey, such as Potatoes and grain, and partly to the increasing difficulty of procuring the Moss.

THE GARDEN.

"This is an art

Which does mend nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

THE ROSES OF 1874.

By S. REYNOLDS HOLE.

(Continued from p. 213.)

It may be expected that writing in Ireland, I should say something of Irish gardens; but Nature has made in the scenes which I have visited, such a grand exposition of beauty, that Art seems to hide herself, fearing comparison, and I have had no time to go in search of her. Very rarely do we see here, as in England, the fruitful little orchard and gay garden plot, surrounding the cottage home, but in their place, the invariable patch of Potatoes, that supercilious potentate, the pig, roaming where he pleases, indoors and out, and the grey geese, with feathers inserted in the upper beak, to stay their incursions upon the adjoining Oats. Some benevolent landlords, such as Lord Kenmare and Mr. Herbert, in the neighbourhood of Killarney, are improving the dwellings of the poorer classes, and making them bright and cheerful with a garden; but, as a rule, you seldom see any but wild flowers (the exception being here and there a bush of Fuchsia or Hydrangea) about the homes of the peasantry. Again, it must be remembered that the localities through which we tourists travel (mountainous for the most part) are unfavourable for horticulture, both as to site and soil; and also that such residences as would require a garden, and such residents as would desire and could afford elaborate floriculture, are (unhappily for Ireland) few and far between. I have seen, in consequence, only two gardens upon my line of march, but these have been well worthy of inspection, and welcome refreshments to an exiled florist. Walking from Letterfrack to Kylemore, to see the lake, wherein, sixteen years ago, my beloved friend and companion, John Leech, caught the salmon and enjoyed the triumph, which he has drawn so admirably in our "Little Tour in Ireland," I was astonished and delighted to find, where, at my former visit, were only mountains above and a bog below, a spacious and attractive mansion, built in castellated form of a very beautiful stone, with extensive gardens and greenhouses not far distant, and shrubberies and cultivated fields around, the property of Mr. Mitchell Henry, M.P. for Galway. Hearing that Mr. Henry was not only a generous benefactor to those around him, but kindly disposed to strangers also, I ventured within the handsome gateway of his garden, and soon received from his chief gardener, Mr. Garnier, that hearty welcome which all true brothers of the spade rejoice to give and to accept. It is wonderful to see how much skill and perseverance, encouraged and sustained by the good taste and liberality of a wealthy master, have effected at this Castle of Kylemore, and especially in its garden. When we consider the situation, not only exposed to the perpetual humidity of this rainy clime, but to the sweeping storms from the Atlantic, which leave their mark, saline and briny, upon the foliage of the plants; the soil, chiefly peat and gravel, so light, loose, and wanting in tenacity, that the walls of the garden in one part have their foundations more than 20 feet below the surface; and, added to these, the difficulty of inducing Irishmen to finish any hard or large undertakings ("shure, your rivrence," said one of them, "ther's so little work to be found in the country, 'twould be wickied not to make the most of it"); when we reflect upon these obstacles, and then look upon the bright beds and green sward without, and the fruitful Vines, and Pine-apples, and Peaches, and flowering plants within, the desire comes upon us to see a statue of Mr. Henry, like that of Lord Shrewsbury at Alton Towers, placed somewhere between those magnificent beds of roseate Sedum, and bearing the same inscription—"He made the desert smile." Cowan's lime-kiln system is here most successfully applied to some 9,000 feet of piping; the whole range of houses is admirably supplied with water; indeed, all the arrangements (specially the forcing of early fruit) are those of a master mind.

I was indebted to an incident, which in England we should consider remarkable, and which, among our more excitable

neighbours, may not be regarded as abnormal, for a brief visit to another Irish garden which pleased me greatly. To vary our route, as we returned from Connemara, we proposed to travel from Cong, down Lough Corrib, to Galway; but, when we arrived at the former place, we were told, to our dismay, that there had been "just a taste of a scrimmage" between the captain and the engineer of the steamer, and that, consequently, the vessel in question was lying motionless in Galway harbour. So we went to see the celebrated caverns, and, being a giant, I became so convex in Cong Cave, and so suffocated from the smoke of the straw torches, by which it was illuminated, that I was heartily glad when the sight was over, and we went "bedward ruminating." Next morning, we dispatched a message of inquiry to Galway, or rather to the post office at Cong, for it got no further, but was returned to us in a couple of hours with the compliments of the authorities and the pleasing information that the wires (emulating the steamer) declined to work that morning. Our only escape from this dilemma was to hire a couple of cars; and, as these would not be ready for an hour or so, I took the opportunity of visiting the park and gardens, just outside the village, belonging to Sir Arthur Guinness. More picturesque grounds it is difficult to imagine, beautifully timbered, intersected with rivers of waters, which flow by the ruins of Cong Abbey into Lough Corrib, at the head of which, and commanding lovely views, is the house, spacious already, but in process of extensive enlargement. How did I know, before I saw the gardens or the houses, that both would be as they should be? Because the gardener, Mr. Ellis, came to me with his coat off, "his brow was wet with honest sweat," and there was nothing of the cockscorn about him, except some excellent specimens of the plant which bears that name, and which were large enough and velvety enough to have made easy chairs for some fairy nobleman at his club. Therefore I found, as I anticipated, healthfulness and cleanliness, both in greenhouse and stove (for it is indolence which brings dirt, and it is dirt which brings, in the form of animalcule, "a plague on both your houses"); and, in the garden, some 20,000 bedding-out plants, well-grown and tastefully arranged—the colours artistically blended, with an ample intermixture of ornamental foliage. It is known that we, who write for *THE GARDEN*, are not much enamoured of gaudy horticulture. We think that flora looks best in simple garb; and, when we see her in yellow satin and rouge, we move aside as from some object whereupon is written, "Take care of the paint." But I, for one, have ever maintained, notwithstanding, that bedding-out, skilfully handled, and applied as an adjunct, not as a monopoly, may add much beauty to a garden; and it is thus successfully introduced in the pleasant grounds of Cong. You walk between two bright lines of flowers (and this walk, Mr. Ellis informed me, is to extend next summer for a quarter of a mile), but your eyes are not dazzled or wearied, partly because the combinations and contrasts (I have especial remembrance of the blue-grey *Ageratum* in conjunction with one of the pink *Geraniums*) are so aptly arranged, but chiefly because there are ample margins and diversified views around. These glowing beds are but as the ornamental jewels, the necklaces and bracelets, of some winsome maiden, which enhance, but never vie with, her beauty. I would as soon live in Madame Tussand's collection of waxwork, or, like Mrs. Crumles, in the final tableau of the drama, standing upon her head and surrounded by blazing fireworks, as be constrained to dwell in certain gardens which I have seen exclusively absorbed by "bedding out." The first sight, I admit, is a surprise and an enjoyment, but when you have been twice round, and there is nothing else to see, and nowhere else to go, I must say that I am influenced by a great desire to copy the conduct of a small dog, whom a peacock of my acquaintance followed persistently, displaying, whenever the dog would look at it, his gorgeous tail—he barked sarcastically on the thirteenth exhibition, barked, and ran away! Not so with these gardens of Cong, for their beauty is never obtrusive; but we must leave them in a hurry, or we shall never get to Galway in time for the train to Limerick; and, moreover, it may be as well to remember that in this article upon Roses we have not (*more Hibernico*) said a word about them.

(To be continued.)

NOTES OF THE WEEK.

— We have received specimens of the Japan Nerino from Dr. Wallace of Colchester; it grows in sandy places by the waysides near Yokohama, flowering in October, and sending up its leaves in early spring. The trusses of bloom on native plants are about 6 inches in diameter, and the flowers of a deep red. It is likely to prove a useful addition to our garden flowers.

— A NEW winter-garden and aquarium are to be opened at Southport on the 16th inst. Their cost is stated to have been £100,000. The heating apparatus for this new place of public resort has been supplied and fitted up by Messenger, of Loughborough.

— MR. WILLS, the deservedly popular floral decorator, has now taken a third nursery, this time in the Fulham Fields, at Lewis Place. This will be devoted to Palms and cool Orchids indoors, and to Roses out-of-doors. We recently saw in his Amsley establishment a fine plant of *Jasminum grandiflorum*, planted out and trained up the roof of one of the plant houses. So treated it grows freely and bears a profusion of white star-shaped sweetly-perfumed flowers, which are found most valuable for bouquets or "button holes."

— THE Pine forests on both sides of the boundary dividing the provinces of Nyland and Tavastehus, in Finland, appear to have been suddenly desolated by the ravages of a great caterpillar. The *Helsingfors Dagblad* describes this plague in minute terms, which leave no doubt that the insect is the larva of a hawk-moth, in all probability *Spinx Pinastri*. More than 6,000 acres of forest have been entirely destroyed, the larvae stripping off leaves and bark, and leaving nothing but this year's shoot.

— A MOVEMENT is on foot to get the gardens at Kew opened earlier than one o'clock on week days, an hour inconvenient for the public generally. Large numbers of excursionists who come from a distance are disappointed at finding the gardens not opened till the afternoon. Many of these are poor people, who only obtain a holiday once or twice a year; but this is not the only class that suffers, for many other persons would visit the gardens if they could obtain admission at an earlier hour. Were they opened earlier than at present the public would, doubtless, appreciate the concession.

— At a recent séance of the Paris Academy no fewer than eleven communications were received relating to the destruction of Phylloxera. A letter from a Vineyard proprietor proposed sowing Tobacco-seed among the Vines; he had found this an effectual remedy, in the case of Artichokes, for destroying an aphid which attacked the roots. Hemp and *Datura Stramonium* were proposed as preferable to Tobacco, on account of fiscal restrictions on the latter. One suggestion was to destroy the insect by electrical discharges. A committee of the Linnean Society of Bordeaux have pronounced, as the result of their researches, that the Phylloxera is not the cause of the disease, but an effect of an organic malady attributable to five causes, which they specify, viz., exhaustion of soil, inclement seasons, bad choice of stocks, and bad treatment, &c. They state that while Phylloxera is an effect, it may aid in deteriorating the Vine.

— THE pretty and curious little *Gnaphalium Leontopodium* is frequently the cause of newspaper paragraphs like the following:—"The Alpine Edelweiss, to obtain which botanical explorers are always prepared to encounter dangers and difficulties, has lured many to their death. The other day a Mrs. Lockhart ascended the Rosegg glacier in search of it, lost her footing, fell from rock to rock, a distance of 60 feet, and was finally found in a state of exhaustion and seriously injured. It is hoped she will recover, to remember, without over-much pain, her search after the Edelweiss." There is no occasion for botanical explorers "to encounter dangers" in seeking for the plant, as we have walked over many miles of mountain meadow with the Edelweiss always within sight, and to be gathered as easily as any other Alpine flower. It is, of course, necessary to ascend to a certain elevation to get the plant, but so it is in the case of scores of others, many of which are much more difficult to obtain than this.

— THE exhibition of insects in the Taileries Gardens is now open. It is divided into two great classes, the useful on one side and those which are injurious on the other. The bee and the silkworm have, of course, prominent places, as also has the spider. Crickets, beetles, and other familiar insects, which we treat as enemies, are placed among the auxiliaries. The direct and indirect utility of the ant is lectured upon by an aged *servant*, who has spent his life in studying the ways of insects in the woods and Vineyards of the Jura. The Phylloxera is an object of peculiar interest to Parisians, because of the rise it has caused in the price of wines produced on the alluvial soils, where it most multiplies. Each insect is pinned to a card, stating briefly its natural enemies, habits, appetites, capacities of increase, uses (direct and indirect), or the ravages it commits in

accomplishing its destiny. In an annex there is a collection of insectivorous birds, each bird having round its neck the bill of fare which its palate and necessities dictate.

— DR. SCHWEINFURTH is busily employed in the arrangement of the magnificent collection of the flora of Africa which he made during those travels which have excited so great an interest throughout the civilised world. We are not, however, as yet, aware of the value of his discoveries from a gardening point of view.

— We understand that the entire stock of the new *Coleus* Duchess of Edinburgh, raised by Mr. Chitty, of Stamford Hill, has passed into the hands of Messrs. James Carter & Co., of High Holborn. It is of compact habit, the leaves being of a rich crimson or carmine-purple, margined with clear golden yellow. It is figured in the current number of the *Floral Magazine*.

— DR. WALLACE sends us specimens of *Milla biflora* (which is in flower in the open air in his garden at Colchester), a most valuable autumn-flowering bulb, producing flowers which are of a clear paper-white inside, the outer side of the division having a clear band of green running up the centre of each, which gives the flowers quite a distinct appearance. It is sweet scented.

— MR. DISRAELI (says a daily contemporary) is fond of, or affects a fondness for, gardening. Perhaps nothing could be more characteristic of the two rival leaders than the circumstance that some two or three years ago, while Mr. Gladstone's "passionately earnest" nature found a congenial relief in felling trees on his Hawarden estate, Mr. Disraeli was, like a second Bacon—*write* the immortal essay "On Gardens"—cultivating his Roses at Hughenden.

— THE much-talked-of Colorado Potato beetle has at last made its appearance in the suburbs of New York city. At present, however, the insect is found only in comparatively small numbers, a few of the yellow grubs perhaps being scattered here and there in a field, or clustered on a Potato hill or two in some corner, but there is enough to furnish an abundant brood next spring, because nearly all those which came to maturity this fall are going to burrow in the ground and be ready to multiply their kind next spring. We trust none of them may take passage, by one of the quick steamers, to this country.

— It is stated by the *Graphic* that Trafalgar Square is about to be beautified by the Duke of Northumberland, who intends to spend some of the purchase-money of Northumberland House in making a garden of it. A bed of dwarf evergreens will surround the Lansdown lions, and the dismal stone flags will give place to neat gravel walks and parterres of flowers. We trust the Duke may not be misled into planting many evergreens in this position. What is most wanted are some good deciduous trees that will do well and improve from year to year. These need not exclude a graceful arrangement for flowers or such evergreens as are really suited for the position.

— WE never remember to have seen Covent Garden Market better supplied with fruit than at present. Some fine Pines have just arrived from St. Michael's in excellent condition. Grapes are imported in large quantities from Lisbon, and also from Jersey. These are of good quality, and realise, on an average, sixpence a pound. Figs from Worthing and the Channel Islands (Guernsey) are plentiful. English Melons are now in season, and large quantities of Melons also come from Spain (Denia and Cadiz). Apples, Pears, and Plums, of home growth, are excellent in every way. Bananas and Prickly Pears are now arriving in quantity, and there seems a plentiful supply of Filberts, Cob-nuts, and Walnuts.

— Those who are interested in decorating public buildings with living plants should not fail to inspect Messrs. Dick Radclyffe's pretty arrangements, now to be seen in the concert promenade of Covent Garden Theatre. They consist of rock-work made with tufa half hid among Ferns, Palms, Cyperus, and similar plants, that over-hang pools of running water. For such pretty devices, crowded gas-heated saloons are not the best of places; hence some ingenuity and tact are necessary in order to preserve the plants used in a healthy condition as long as possible, and in this somewhat difficult art Messrs. Radclyffe have succeeded admirably, as the examples just alluded to amply prove.

— WE have received a splendid spike of the Zebra-striped Oncid (*O. zebrinum*) from Sir William Marriott's collection at Down House, Blandford, Dorset. Its total length was 12 feet, numerous branched. The individual flowers measure about an inch and a half across, the sepals and petals being undulate or heavy, and white in colour, marked with purple blotches and bars. The dagger-shaped lip has a large corrugated crest of a bright yellow colour, and the habit of the plant is nearly identical with that of the Peruvian *O. macranthum*. The plant flowered in the Manley Hall collection about two years ago, but neither flowers nor flower-spike were so fine as in the present instance. Mr. Hill, who has grown the plant, kindly informs us that it luxuriates in a cool Odontoglossum-house facing the north, and that it likes an abundant supply of moisture.

LADDERS FOR PICKING FRUIT.

LADDERS are absolutely essential to careful hand-picking, unless it be from dwarf trees. The more convenient the ladder, the easier and more expeditious the gathering. An important requisite is to use ladders in such a manner as not to cause any bruising to the branches. For moderate heights, step-ladders are best, and most easily carried. A simple and convenient one is shown in fig. 1. It is a three-legged stool, about 2½ feet high, with stout spreading legs, inserted into a piece of tough plank at the top, with connecting rounds on one side, set so that one can easily step up on the plank. The legs should be slightly longer than a common chair post. The advantages of this simple ladder-stand are, it can always be

Fig. 3. Pointed Hooked Ladder. Fig. 2. Long Hooked Ladder. Fig. 1. Short Standing Ladder.

easily carried in one hand, is always ready for use, stands firmly, and enables the picker to reach branches which are a short distance overhead. When the fruit is higher, the common short simple ladder answers well (the length varying from 7 to 15 feet), provided certain modifications are secured for holding it firmly in the tree, and to prevent bruising. A common ladder does not always stand firmly, and is liable to slide to one side or the other, to the peril of the picker and the danger of bruising the bark. To guard against these difficulties, let one of the bars extend beyond the other (by cutting the end of the other off, if the ladder is already made), and add to it a broad wooden projection or hook (fig. 2). This hook is screwed firmly on the bar, and to prevent bruising, should be

Fig. 4—Standing Ladder.

padded beneath. By resting this in the fork, between two smaller branches, the ladder will stand perfectly secure. A modification of this ladder is shown in fig. 3, and consists of bringing the two bars together at the top, with the hook attached to both. Being thus in the centre it rests more firmly, and the wedge-form of its point allows it to be thrust freely into any part of the tree.

Standing ladders, of larger size than the one shown in fig. 1, may be constructed after the form in fig. 4. It is simple, and, if properly made, is light and portable. It may be 6 or 8 feet high; the higher, the wider should be the spread of the legs at the bottom. To prevent the rounds from being weakened by this breadth, a few of the longer and lower ones are made to pass through a central stiffening bar, so that one will possess

the strength of the three. The simplest mode for hanging the legs at the upper end is to bore holes through them near to the top, and pass the upper round through these holes; or, iron hoops may be screwed on the upper ends of the legs so as to pass about the upper round. When not in use, the legs are readily folded against the ladder, and it is easily carried from place to place, or placed snugly under shelter.

A common ladder, when not over 12 feet long, may be easily made into a standing one, by means of the contrivance exhi-

Fig. 5—Long Standing Ladder.

bited by fig. 5. Two supporting legs are attached to the outside bars at the top by means of screws, the form of which is shown at *a*. The legs have an opening or slot (*b*) to receive these screws. The ladder is raised, and the legs are at once

Fig. 6—Common Ladder changed to a Standing one.

placed under, against the screws, where they remain securely till the ladder is moved.

Fig. 6 shows the upper end of the ladder more distinctly at the place where the legs are attached. The screws should

Fig. 7—Tie Rods.

Fig. 8—Fruit Ladder.

be set a little obliquely, so that the legs may spread. A blacksmith will make them at a small cost. All ladders like this should be shod with iron or steel at the bottom, to prevent slipping. Slender ladders often get out of order by the legs or bars springing in the middle. To prevent this springing, the occasional insertion of tie-rods answers perfectly. Take a piece of half-inch round iron rod, make a head

at one end, and a small shoulder at the other, with a screw and nut outside, and when the ladder is put together, insert the ties. Fig. 7 shows one of these ties separately, and another inserted in the ladder just below the round.

Fig. 8 represents a contrivance for supporting the fruit basket while the picker is filling it. It is made of rod-iron, half an inch in diameter, bent, when red hot, into the form shown at *a*. This, when inserted into the two holes, bored with a half inch augur just below each step, forms the support. Smaller rods may be used if cross pieces at the dotted lines are welded on. The more common way of supporting the basket (so as to leave both hands free to the picker), is by simply attaching a small wooden or iron hook (fig. 9). The wooden hook is made of a forked branch of a tree, tied to the handle of the basket; the iron hook of bent rod. Any carpenter may make any of these ladders; or the cultivator who has a workshop may readily make most of them for himself on rainy days.

Fig. 9.—Hook for Basket.

THE DESTRUCTION OF THE VINEYARDS OF FRANCE.

ACCORDING to the Paris correspondent of the *Daily News*, the Vine pest, *Phylloxera vastatrix*, is decidedly the lion of the dull season. "Have you seen the *Phylloxera*?" the *quidnunc* asks you on the boulevards. Talk to a householder about the Prussian corvettes in the Bay of Biscay, and he will tell you that the *Phylloxera* interests him more. The wine merchant has raised the prices of ordinary wines, on the plea of the devastation caused by the *Phylloxera*. If you ask for the coarse cordial wines of the Rhone, the Gard, or the Durance, you are told you can have a few bottles as a curiosity. At the few dinners I have lately gone to, the *Phylloxera* was the burden of the conversation. Each day, at the Insect Exhibition, there is a long line of householders and housekeepers before the glass case where the Vine-destroying insect is on show. A *savant*, with a microscope, explains its habits and history. You hear the sightseers sing out in chorus, "The brigand!" "The monster!" "The frightful glutton!" And a frightful glutton it is. Its appetite and devastating mission are indicated in its structure. Even seen through a magnifying glass, the head is scarcely perceptible. The belly is ponderous and loosely attached; the legs are thin, short, and rickety; the body shaped like a viper's head, or the collar of a short and very stout person; the nose is armed with a long probe and cupping apparatus, with which the insect pierces the bark of the Vine, and absorbs the sap which should nourish the plant. The wings are attenuated, but the *Phylloxera vastatrix* being easily transported by the wind, does not suffer from insufficient means of locomotion. Its ashy colour enables it to pass unperceived by the husbandman, who, unless he looks close to the stems of his Vines, would take the plunderers congregated on them for a coat of dust. In connection with the present Exhibition an eminent entomologist, M. Duclaux, Professor of Chemistry to the Clermont Faculty of Sciences, has drawn up a series of maps showing the progress of the *Phylloxera* invasion. The enemy was first noticed in France in 1865 on the plateau of Pujant, not far from the Pont de Gard. The invaded district is marked in the first map of the series with a red point not bigger than the eye of a fine needle. Somebody who had travelled in America warned the cultivator, on whose Vines he saw the invader, to lose no time in setting fire to the plants attacked. But the warning was disregarded, as coming from a man who notoriously had a hobby for small birds. "Our Vines won't be any the worse for it next year," was the answer of the too confident husbandman. In 1866 the enemy had spread north, south, and east across the plateau, which is marked in the second map with a big red spot, the shape of a hatchment. The northern point of the crimson stain touches the village of Roque Maure, the southern Villeneuve, and the eastern, the Rhone. There is also an eruption of pimples, which are thickest near Carpentras, Tarascon, and Arles. In 1867 these pimples became a broad stain. We notice in the third map two great centres of disease. The first, a long quadrilateral, traverses diagonally the Rhone, embracing the plain of Orange, the environs of Avignon, that broad flat called Le Plan-de-Dieu, and the alluvial land round Sorgues. The second is an oval patch, covering the fertile portion of the Crau. In 1868 there was a union of these centres. The invader marched by Cavallon and fat Perthuis, up the Durance Valley, sending out detachments to right and left. Two columns descended to the Mediterranean, attack-

ing the goodly Vines about Toulon, where, before the *Phylloxera* appeared, a bottle of wholesome strengthening wine could be bought for a couple of sous. A third column struck in a zig-zag direction across the Vaucluse. The northern boundary of the invaded country in 1868 passed from Parrelatte to Grignan of de Sevigne celebrity in the department of the Drôme. In 1869, the fourth year of the insect war, the red stain had extended to the foot of the Ventoux and the Vaucluse chain, which have barred the way farther east on the *Phylloxera*. But the Luberon and Alpines were not a serious impediment to the invader, which turned them in a few weeks. In 1870 there was a halt. This was in the beginning, a phenomenally dry and hot year, and, from the end of October, exceptionally cold. In 1871, the enemy, as if refreshed by the halt, advanced with greater speed than ever. He pushed north of Valence, smiting Chateau Neuf du Pape, and other celebrated Vineyards. This year (1871) the ravaged country appears in the form of a triangular stain, of which the base crosses from Montpellier to Frejus, and the apex is marked at Tain. A perpendicular line falling from this point to the Mediterranean would cover 200 kilometres of wine-producing country. Hitherto the march of the *Phylloxera* has been north, south, and east. In 1872 the enemy sent a detachment across the department of the Herault, carrying all before him. By this time 1,100,000 hectares of rich Vineyards were devastated. In 1873 the triangle lengthened to Vienne. The Gers, the Garonne valley up to Agen, the Rhone valley as far as Lyons, and the part of Burgundy between that town and Macon were covered with a red eruption, which has not yet spread into stains. The *Phylloxera* chiefly encamps in plains and valleys. It does not like high ground, and never crosses mountains, which, however, it skillfully turns. Clayey soils lend themselves to the progress of the terrible insect. M. Duclaux does not endorse the comforting assurance published in some agricultural prints, that the *Phylloxera* can be destroyed by irrigating the plains where it encamps. For the present, nothing better has been hit upon than to root up the attacked Vines and burn them, thus destroying the germs of the insect. The natural remedy, small birds, can only be obtained with patience, and it remains to be seen what particular bird is the born foe of the Vine-destroying insect. M. Duclaux's maps have been drawn up at the request of the Academy of Sciences, which has devoted two sittings to an examination of them. M. Lichtenstein, a French entomologist, who for six years has been investigating the habits of the *Phylloxera*, has addressed a letter to the Minister of Agriculture and Commerce, in which he shows how the ravages of this insect may be checked. During the present month the *Phylloxera* is winged, and repairs in enormous numbers to the trees which border the Vineyards, where it deposits an egg, or rather a chrysalis, whence a perfect insect emerges. The insect immediately breeds, but he has not yet ascertained how the offspring reaches the Vines. He recommends the Vine-grower to singe the tree—a kind of Oak, of no value—on which the *Phylloxera* has settled, and thus destroy millions of insects.

A NEW KIND OF TOWN GARDEN.

At Stamford Hill an interesting example of the "flat" system of building houses, to meet the requirements of middle class people, has been built by Mr. Allen. The usual foolish arrangement of narrow slips of gardens surrounded by fences has been done away with for a much better one, which we find thus described in the *Scottsman*:—"The most novel feature of the plan is the garden. To houses of this class in the suburbs of London is usually attached a narrow strip of garden ground, either walled-in or separated from its neighbours by rows of ugly black railings perfectly useless for the purpose of privacy, seeing that the enclosed space is overlooked by the windows of the whole row. Mr. Allen has done away with all this useless lumber, and has thrown the grounds of the houses into one. Still, each house has its own little lawn on which the children can play at special games, or the young people at croquet. These lawns are divided by walks and flower borders, and opposite the houses, which are built in line and open to a pretty bit of wooded country, rises a miniature Crystal Palace in the shape of a long row of greenhouses, built with great taste and elegance. In the centre of these is a square building of two storeys, opening into the conservatories, the first-floor of which is a sort of bower for the ladies, a retreat from sun or shower, where they can bring their books or work and sit in summer. Above, is a billiard-room for the gentlemen. A head gardener, with one or two assistants, is to keep the grounds in order, and this part of the scheme is already carried out. The conservatories are full of choice plants and Vines, which have borne their first fruit. Peaches, Apricots, Melons, and all the finest sorts of fruit are grown, and are to be disposed of to the tenants if they desire to purchase them at a fair price, and, after they are supplied, to the public in general."

THE GARDEN IN THE HOUSE.

BULBS FOR WINDOW AND ROOM GARDENS.

IMPORTED winter and spring flowering bulbs are now arriving in large quantities, and now is the time to commence the cultivation of such kinds as are required for early flowering. The best for this purpose are Narcissus, such as Paper-white, double Roman, and Soleil d'Or; Hyacinths, of which the single forms are best, Snowdrops, Crocuses, and Tulips. These should be potted at once in a light rich compost, while a few bulbs of Hyacinths and Narcissus may be grown in glasses of water, for the sake of variety. In selecting bulbs it should be borne in mind that medium-sized roots, well shaped, solid, and compact, are preferable, and more likely to give satisfaction than large spongy bulbs; as, when found in this condition, it is a sure sign that they are not thoroughly well developed or ripened. All bulbs should be potted as soon as received, for, if allowed to lie about, they lose much of their energy by the evaporation that takes place from their surface. The best compost to employ is one consisting of one-half fresh turfy

A Perforated Vase for Spring Flowers.

or fibrous loam, to which one-third of peat and leaf-mould is added, and one third well rotted hot-bed manure, adding sufficient coarse road sand or sandstone grit to keep the whole in a fresh and open condition. The pots used should be scrupulously clean and well drained. In potting, place the bulb in the centre of the pot so that the crown is just below the soil when the operation is finished, and the surface should be left perfectly level and firm about half-an-inch below the rim of the pot. This is not actually indispensable to success, however, as when bulbs are planted in the borders outside they are covered with 2 or 3 inches of soil. After potting, the roots should be set in rows nearly close together, under a north wall or fence, and covered with sand or sifted coal ashes to a depth of from 3 to 4 inches. This covering serves two or three purposes, it protects the bulbs from cold and frosts, and prevents their forcing themselves out of the pots when making their roots, and it also keeps the compost round them in a state of genial moisture, and does away with the necessity for watering. The plants root freely and throw up their crowns in a few weeks, and are then ready for forcing, or for removal indoors to bloom. The sand also serves a very useful purpose in retarding the

plants that remain, so as to keep up a succession of flowers after the first spikes open. After removal indoors, the pots should have a light airy position, and will require liberal supplies of moisture at the root. A little clear manure-water will prove very beneficial when the pots become filled with hungry roots, which generally happens just as the spike approaches maturity. Crocuses, Tulip, and Narcissus bulbs may be treated just in the same way; only the smallest bulbs may be inserted three or more together, in a 48 or 32-pot. The accompanying illustration represents a globular Crocus pot, pierced with holes, opposite each of which a Crocus bulb is placed, and the intervening spaces are filled with compost. Some use moist Sphagnum in place of soil, and, if the bulbs are well ripened, it answers nearly equally well. A Hyacinth bulb, planted at the top, finishes off the arrangement in a pleasing and artistic manner. Crocuses and Snowdrops, if planted any time before November, in the window-boxes outside, will flower freely during the first bright sunny days of spring, and give a very cheerful appearance to the window-sill, especially if the bright tints of the early blossoms are contrasted with fresh green Ivy, Box, Aucubas, Periwinkle, Euonymus, or other free-growing hardy shrubs and climbing plants. Hyacinths and Narcissus bulbs may now be placed in common Hyacinth glasses, filled nearly full of tepid water. Care should be taken to prevent the base of the bulbs touching the water below, and if a space of about half-an-inch is left between the roots, attracted by the moisture, soon protrude from the base of the bulb, and find their way down inside the glass. If this point is not duly attended to, it often results in the bulbs rotting away at the base, and this is especially the case if they are unripened or loose in texture. Few early-flowering plants give greater satisfaction to the amateur than these, as they are so easily grown, and flower so quickly after being potted. In addition to those mentioned above, flowering bulbs of both the Belladonna and Guernsey Lilies may now be purchased for a few pence each, and these, if carefully re-potted at once in any light rich soil, will flower in a week or two, and will keep the window gay until Hyacinths and Narcissus develop their delicate wax-like richly-perfumed flowers. It is a good plan to surface the spots containing bulbs with fresh green Moss, if it can be obtained, as it not only gives a fresh and pleasing appearance to the window, but keeps the roots below in a more equable state as regards moisture. All the above will grow well in an ordinary window if duly attended to, but if there is the additional advantage of a Wardian case or window conservatory, they may be forwarded thereby so as to flower much earlier. Last year I placed newly imported Hyacinths—in glasses of soft water—on the mantel-shelf in my sitting-room, and these received no extra attention, except giving them a fresh supply of tepid water every week. Bulbs so treated, if well ripened, flower in about six weeks after they are placed in the glasses, and last a long time in flower.

F. W. B.

DINNER-TABLE DECORATION.

Vases for the Drawing-room.

LARGE vases, I always think, look out of place in drawing-rooms, where all that is required is just a few flowers, gracefully grouped in small vases, and a few specimen glasses placed here and there. At the exhibition of the Royal Horticultural Society, held at Birmingham, in the class for drawing-room decorations, I was fortunate enough to take the first prize, with a trumpet-shaped vase having three curved branches, and dressed as follows:—In the bottom dish or tazza, were three Water-Lily blooms, and some Maiden-hair Fern, the edge being ornamented with a few fronds of Lastrea filix-mas; the three curved trumpets were filled with blue Corn-flowers, white Sweet Peas, Maiden-hair Fern, &c., and the top was decorated in a similar manner, but contained, in addition, white Rhodanthe and wild Grasses, while amongst the trumpets trailed long sprays of the pretty Lygodium seandens. A smaller stand, to which was also awarded a first prize at one of the Crystal Palace exhibitions, struck me at the time as being most elegant and chaste in form. It consisted of merely a very small flat glass dish, with a slight trumpet rising out of the centre; in the tazza were merely three Water-Lilies,

some green Oats, and a few Ferns; in the trumpet were simply Oats and Rhodanthe, flowers of no great importance, but at few exhibitions has there been a more charming little arrangement. I have even seen neat little stands, which consisted merely of an ordinary specimen glass set in a tea-cup saucer. Thus the saucer may be filled with yellow Rose-buds, Neapolitan Violets, leaves of sweet-scented Geraniums, and a few fronds of *Adiantum cuneatum*, the edge being finished off with a thick wreath of Fern fronds; in the little trumpet or specimen glass were placed a few sprays of *Deutzia gracilis* and Ferns. Specimen glasses of a somewhat large size, with a few flowers placed in them also, form pretty decorations; but the flowers selected for this purpose should be of the best sorts, and perfect specimens of their respective kinds. One which I saw at the house of a friend, and which I much admired at the time, contained some spikes of Cape Heaths, a bloom of *Pancreatium fragrans*, and a few drooping bells of a small pink Cactus, the bouquet (if I may so call it, though it was not tied) being backed up by some fronds of hardy Ferns; against these were placed the Heaths, then the *Pancreatium*, and the Cactus blooms drooped over the edge, the whole being shrouded by Maiden-hair Fern. Orchids are flowers just suited for vases of these descriptions; what, for instance, looks more elegant than a few blooms of *Dendrobium nobile*, mixed with a few spikes of Lily of the Valley, set in a miniature bower of *Adiantum cuneatum*? Hyacinth glasses are also very suitable for drawing-room decoration, especially those having opaque grounds ornamented with gold. These may contain larger blooms than those mentioned for trumpet-shaped glasses, as, for example, Roses, Fuchsias, Pelargoniums, Cactuses, and others; but, associated with these, as well as with flowers of smaller sizes, should be wild Grasses, so blended as to give a light look to the arrangement. Oats, in a green state, as I before mentioned, are useful for this purpose, though not so light looking as ordinary Grasses; both, however, may be purchased in bunches during summer in Covent Garden, therefore, both town and country readers have an opportunity of testing their value.

A. HASSARD.

ALPINE PLANTS AND HARDY BULBS ON THE WINDOW SILL.

This is now the fourth season since my outside window-garden was planted, and it has gone on improving so that in the hottest day of summer and the coldest day of winter it is full of attraction. Saxifrages, Sedums, *Sempervivum*, *Campanulas*, *Lithospermum*, &c., are one or other in flower; and as regards bulbs in autumn, we have the *Sternbergia*, *Zephyranthes*, autumn Crocus, and *Colehiem*; following these come the Snowdrop, the spring Crocus, and *Scilla sibirica*; and in window gardens, where a greater depth of soil is given, the Hyacinth and the Narcissus may be introduced with advantage. The construction of the outside window garden may be stated to be of the simplest possible character, so that anyone can make it, or have it made by an ordinary carpenter. We used yellow deal, and the width may range from 12 inches to 2 feet according to space. At the back of the garden is a strip of wood 3 inches in height, which may be made higher or lower according to taste, and scalloped or plain. The front should be somewhat ornamented. This structure, while resting upon the sill of the window, is raised on blocks a quarter of an inch to allow of drainage, and preserve the sill from damage. The soil used should be a good compost consisting of road-scrappings, loam, and leaf-soil, the surface undulated according to taste, working in judiciously a few stones or shells, so as not to be conspicuous, and then planted to be the most attractive from the room. Between the scallops or ornamental part of the woodwork in the front, trailers should be inserted, so as to have the best effect, with *Sempervivum* as rosettes; or, if a rustic facing is given to the garden, Sedums, Saxifrages, and other rock-loving plants do well. When shells are introduced, small growing *Sempervivum*, such as *montanum*, or the Cobweb House-leek are the most desirable to plant in them. The class of plants which I consider most desirable for a window garden are the dwarf-growing Alpine plants, with just sufficient elevation to break the lines, and from the following genera a good selection can be made:—*Alyssum*, *Androsace*, *Antennaria*, *Arabis*, *Arenaria*, *Armeria*, *Arum*, *Aster*, *Aubrietia*, *Bambusa*, *Bellium*, *Campanula*, *Dianthus*, *Draba*, *Dielytra*, *Eleocharia*, *Erinus*, *Hepatica*, *Iberis*, *Iris*, *Linaria*, *Linum*, *Lotus*, *Lithospermum*, *Lychnis*, *Lysimachia*, *Myosotis*, *Nierembergia*, *Oxalis*, *Phlox*, *Potentilla*, *Primula*, *Sibthorpia*, *Soldanella*, *Spergula*, *Saxifraga*, *Sedum*, *Sempervivum*, *Silene*, *Thymus*,

Viola, *Veronica*, according to situation and aspect. Of bulbous plants, add *Sternbergia lutea*, with its large yellow Crocus-like flowers in autumn; *Zephyranthes candida*, with its silvery-white blossoms in autumn, the autumn Crocus and the autumn Scilla; and for spring blooming, the intense blue *Scilla sibirica* and *bifolia*, the spring Snowflake, the Snowdrop, the Crocus, the miniature Hyacinth, the *Narcissus Bulbocodium nans*, and *minimus*, the *Bulbocodium verum*, the dwarf early single Tulips, *Iris persica*, and *reticulata*, and, besides these, many other bulbous and tuberous-rooted plants would contribute their charms, so that within a limited space a garden may be had with representatives from every temperate clime. The invalid who can only be moved in a chair can tend this garden, while those who are much confined indoors have only to turn their eyes to the window to enjoy a pretty miniature Alpine garden. To children it is a delight. In their culture there is no difficulty, and the window garden once planted simply requires to be kept free from weeds and attended to with water.

PETER BARR.

THE FRUIT GARDEN.

TRANSPLANTING FRUIT TREES.

MANY say that fruit trees should be moved as soon as the leaves are off. The soundness of this view depends, I think, in part on the conditions under which the removal takes place. If the trees have to be procured from a nursery or elsewhere at a considerable distance from their destination, so as to entail their being any time in transit, no doubt, just after the fall of the leaf is the best; inasmuch as, if removed whilst the leaves are yet quite green and plenty of vitality in them, with the consequent sap in the wood, the bark would shrivel and the leaves wither and fall at once, to the certain injury of the trees. But there are very many occasions when it becomes necessary to remove fruit trees where the distance of removal is short—such as in thinning out when trees have become too close, or where alterations have to be made requiring the ground they occupy for other purposes. In removals under such circumstances that from time to time I have had to effect, from the beginning of September until the end of February, I have carefully noted the result; and, except in the case of quite small trees that had recently been moved, or very large ones that had in no way been prepared by previously cutting back their roots, I always found the earliest period after the fruit-buds were set the best for several reasons. In the case of Peaches, Nectarines, Apricots, Apples, Pears, or Plums, that have been planted from say four to a dozen years, these should always be prepared by cutting their roots well back the autumn twelve months previous to planting; this, as is well-known, checks the vigorous disposition of the trees, and causes them to form quantities of small feeding rootlets near home, which, by the exercise of reasonable care, can be removed without a great amount of mutilation, and are at once in a condition to act. Take, for instance, Peaches; when a new wall is furnished, the trees are usually planted doubly as thick as there is ultimately room for; consequently, the time comes when every second tree has to be removed; these often come in to fill up blanks, or possibly to furnish a Peach-house. The question then becomes—at what time can they be removed so as to entail the least loss of time in their producing fruit in their new position? In such cases as this, with reasonable forethought, every facility exists for preparing the trees, and transferring them without delay, and with the least possible mutilation of the roots, to their new quarters. And then, without hesitation, I should say remove them as soon in the autumn as the bloom buds are set, and the fresher and more leaves they have the better. Of course, this implies that they are thoroughly soaked with water when planted, and kept well supplied with it, so long as the weather is such as to require it, and if a few mats are hung before them in sunny weather they will be none the worse for it, in addition to syringing overhead. Trees removed early and so treated, will make considerable root progress before the winter; during which, as a matter of course, the roots will require protection by mulching, and the trees may be expected to carry a fair crop the season following. The same holds good with Plums, either on walls or in the open ground; and during the season following, both must receive plenty of water in dry weather, as any stone fruit

that has received a check at the roots will suffer more from a deficiency of water than either Apples or Pears. I have seen a Plum tree that the season after being removed as described set fruit thickly, and threw the greater part off at the time it ought to have stoned; while another tree of the same variety (Victoria)—moved at the same time and similarly treated in every way, except that it received plenty of water—finished a full crop, the individual fruit, however, not being so large as if removal had not taken place. This early removal of Apples and Pears has a similar effect upon these fruit; but with Apples early planting has an influence that extends beyond the first year after removal. Anyone who has had experience in the removal of Apples when the trees have arrived at a considerable size, or that have root-pruned somewhat severely any which were over-vigorous and unfruitful, will have noticed that for two or three summers afterwards the trees would make but little growth, and most likely be severely attacked by red spider, which, if not destroyed, would prevent the fruit from attaining its natural size, even the second or third season after transplantation—a circumstance obviously caused by the trees beginning to push growth in the spring after removal, before there were any feeding roots at work to supply the exigencies of leaf and shoot formation. If the trees are removed early in the autumn, as suggested, this stunted condition does not follow.

One thing is common to all standard, pyramid, or even bush trees that are removed after having arrived at any considerable size—they must be thoroughly secured by stakes for a couple of years afterwards until they have got good root-hold, so as not to be shaken by the wind; for, if they work about at all, they never can, by any possibility, lay proper hold of the soil. In the case of Currants and Gooseberries that have got a good size, these fruits, if removed late in the season, as will have been noticed, make very little growth for several years afterwards, all the energies of the trees being directed to bearing fruit, which is generally, under such conditions, small; but early removal has a considerable influence in causing freer growth and larger fruit. Large trees, that had attained considerable age, it would not be safe to remove until all their energies were at rest. I have seen large vigorous-growing Pears 18 feet in height, that had occupied the gable ends of buildings, removed and do well, bearing much freer in the course of a couple of years after than ever they did previously; but, in the case of such trees as these, I should not attempt their removal until all the leaves had fallen. In the planting of fruit trees in general, especially in private gardens, there is an almost general disposition to plant too many varieties in the case of Plums, Apples, and Pears. An exhibition of several hundred varieties of Apples and Pears is an interesting display; but, so far as affording data sufficient to enable anyone to make a judicious selection for planting in any part of the country, it is worse than useless; inasmuch as the appearance of a dish of fruit, even if an opportunity existed for tasting the quality, is very far from being certain evidence of the advisability of attempting to grow it; the reason being, that nine-tenths of the varieties obtainable are often shy in bearing, weak in constitution, or have some other faults. If the general merits, or suitability, of any variety of these fruits for cultivation in any particular situation could be determined in a season or two, as with Potatoes, the case would be different, and the loss of time and disappointment would be inconsiderable; but such is not the case; Pears, even when grafted on the Quince, and Apples, on stocks that have the earliest bearing disposition, take some years to prove their fitness for any particular locality.

Previous to planting fruit trees the best and only reasonable course is to ascertain the varieties that are found to answer most satisfactorily in the neighbourhood. This is the most certain guide to follow, so far as the principal planting goes; if there is an inclination to try any newer varieties that make their appearance, or any promising sort that may not have been tried in the immediate district previously, no harm can be done; but, for the general supply, always depend upon sorts that have been proved on or near the spot, even if they are slightly inferior to others with which you may be acquainted. This more particularly applies to Apples, and that to culinary varieties; for, justly

prized as are good dessert sorts, still it is to the cooking kinds to which the greatest importance is attached, for of all the fruits we grow there are none that bear any comparison with these for general use. My impression is that there is nothing in the shape of food more conducive to health than cooked Apples, especially such varieties as are somewhat acid. The frequent recurrence of late spring frosts, that for the last twenty-five years we have experienced, has rendered many of the early-flowering or tender sorts of little use. The present season, if turned to proper account, should teach us much as to the varieties best calculated to resist a low temperature during the blooming season. The returns of the fruit crop throughout the country are both interesting and useful; but if, and especially in such a season as the present, a return was made from each division of every county as to the varieties that are carrying good, moderate, light crops, or total failures, more reliable information would be afforded than has ever yet been obtained as to the great essential—hardihood of the varieties in cultivation. This year such information would carry more than usual weight, as we have seldom had a season when not only every variety, but almost every healthy tree, was so fully ripened and covered with fruit buds as was the case last autumn. I noticed many trees of large size that had got into the very usual habit of fruiting every alternate year, with scarcely a bloom bud upon them in the intervening season, that last summer carried full crops, and set a profusion of bloom buds as well. New varieties of Apples and Pears keep making their appearance, but, as I have repeatedly urged, my impression is that most of the raisers begin at the wrong end. No doubt the raising of new fruits is both interesting and profitable to those engaged in it, and deserves the highest commendation if they are improvements upon existing varieties; but if not, they are nothing less than an infliction upon those induced to try them, and retard instead of advance the pursuit of fruit culture, being useless to all except those immediately interested in them. The raisers of new varieties of Apples and Pears appear to keep continually working from the best flavoured varieties, regardless of their hardihood; and their productions do not appear to possess any distinctive merits beyond those of the sorts from which they have been raised; often the reverse is the case when the new comer has been sufficiently tested so as to give conclusive evidence of its actual worth. Allow me to be rightly understood; no one is less disposed to council a standstill attitude in anything connected with horticulture than myself, but we had better stand still than proceed in the wrong direction. Instead of raising new kinds of fruits from such parentage as is generally employed, I hold it would be much more advisable to breed from free-bearing hardy kinds, and, above all, such as have a late blooming disposition (an indispensable property, on account of the better chance they have in escaping frost), and endeavour to obtain new sorts with the hardy constitution of those we breed from, combined with superior quality in the fruit. But the groundwork of all improvement must rest on a hardy vigorous constitution. Some time back a discussion arose respecting Apple stocks, and by some who wrote on the subject a disposition to push early in the spring was held up as an advantage. Nothing could possibly be more fallacious on account of the increased danger that would arise to the earliest blooms from frost.

T. BAINES.

LOW ESPALIER FRUIT TREES.

I HAVE lately seen in a garden in the Isle of Wight some Apple and Pear trees trained as espaliers, in height scarcely exceeding 3 feet, most, if not all, of them having four tiers of branches. The low height at which they were trained did not appear to operate unfavourably upon their produce. A Marie Louise and a Bon Chrétien (Williams's) each carried quite as much fruit as any tree ought to be allowed to mature in one season, nor did any of the Apple trees trained in the same manner equal either of these two Pear trees in production. On the Marie Louise I noticed several Pears on the lowest tier actually touching the ground. From their appearance I infer that they were planted about twenty-five or thirty years ago, and they exhibited evident traces of neglect or bad management in past years. The top branches, for the most part, instead of

being the least, are the largest in circumference, and in some instances are covered with a hedge of spurs upwards of a foot in length, and it is only of late years that they have been taken in hand by an experienced gardener. I measured the trees carefully and cannot be mistaken as to their height. We often see in small kitchen gardens 5 and even 4 feet espaliers, where a greater height would be detrimental to the vegetable crops, by unduly intercepting the sun's rays, and interposing obstacles to the free circulation of air. My own experience leads me to think, and my view is supported by what I saw in the Isle of Wight, that height is not essential to the successful training even of the Pear, if the following particulars are carefully attended to. During the first few years each lower branch should be kept well in advance of the one next above it, and, when the tree has reached the limit of the distance allowed, it should be made to take a form that would admit of each lower branch remaining longer than the branch next above it, an example of which may be seen in the form called the Palmette. Another important matter to be attended to, especially in the case of free growers on the Pear stock, is the regulation of the parts whence the bearing shoots proceed. The distance from bud to bud along a last year's shoot varies from about 1 to 2 inches. In the following year most of these buds will be developed into either fruit-bearing or ordinary leaf shoots. If all of the latter were allowed to remain the tree would soon be overcrowded, therefore, the thinning of these shoots from time to time becomes necessary. In the course of years, as the tree advances, bare spaces of 6 inches in length will not be too much to leave clear of shoots, and the sooner the branches are cleared to half that distance the better. Then the branches that form the highest tier will, in about the third year of their growth, begin to give trouble unless they are repeatedly thinned and carefully attended to during the summer. For want of due attention in this direction many an espalier has been hopelessly deformed with what is called a *tête de sautoir*, interesting specimens of which may still be met with in old kitchen gardens. By all means, therefore, begin with your top tier in good time, and if, as is often the case with twiggy sorts, like the Marie Louise, there is likely to be an overcrowding of shoots, cut several of them clean out with a penknife when they are about half grown. With regard to summer pruning with a view to fruit bearing, follow whatever system appears to you to be best adapted to each particular sort, but at the winter pruning take care that your main branches are regulated in such a way as to leave each lower branch 8 or 10 inches longer than the branch immediately above it. Cut away, if necessary, from any one of them the whole of last year's growth, and even more than that if the form of your tree requires it. If, however, any one branch is deprived by an accident of a portion of its length, it may be made to overtake the others by allowing the shoot that springs from the ruptured part to take a gentle curve upwards, training it across the other branches till it reaches the top; in this position it may continue its growth vertically till it regains its proper length, when it may be straightened and laid in its proper position. For Apple and Pear trees in kitchen gardens, the espalier form is so very convenient that it is encouraging to find that even the Pear can be grown with advantage at a height from the ground well within the reach of the operator's hand. In such a form, and at such a limited height, some sorts may not thrive as well as others; but the bare fact that two trees, neither of them so much as 4 feet high, should produce more than average crops, goes far to prove that height, however beneficial, is not essential to the successful cultivation of the Pear.

B. S.

THE PROPER SIZE OF POTS FOR PINES.

YOUR correspondent, Mr. Muir, observes (p. 219), that according to his experience "large pots require much more room than smaller sized ones." It would be useless attempting to dispute such a self-evident proposition, but I would remark that there are pots, and pots, for growing Pines. This subject has been discussed often enough before, and I think nearly all good Pine growers are unanimous in adopting the average 12-inch pot for fruiting purposes. I have visited most of the noted Pine growing establishments in England and Scotland, and, though pots of different shapes are to be found, the 12-inch is the one generally in use. The mere assertion that so and so grows his Pines in 10-inch pots conveys no meaning. There is a form of pot made in

Scotland, and much used for Pine growing there, called a 10-inch pot, but I imagine it will contain about as great a bulk of soil as the ordinary 12-inch or 14-inch one, for it is deeper than usual, and about as wide at the bottom as the top, whereas, in the ordinary shaped pot the bottom is only about half as wide as the top. If your correspondent would give the inside measure, top and bottom, and depth of his pots, your readers could form their own opinion in the matter. I have had Pines from Scotland in those so-called 10-inch pots, and found that they held just about the same quantity of soil as our 13-inch ones, and I have an impression that Mr. Muir refers to the same kind of pot. I am not an advocate for large pots, but I believe in large plants, and would give them the largest pots, as a matter of course. Mr. Muir says that large plants do not "by any means" produce, as a rule, the best fruit, an assertion which I regard as wholly unsupported, either by theory or practice. All other things being equal, the largest plants do, invariably, produce the largest fruit. This is a well-established fact, and not a matter of mere opinion now-a-days. I do not know a Pine grower of any note who does not make it his endeavour to get up the greatest amount of vigour possible in the plants, and plants of the largest size (I am not speaking of elongated specimens); nor do I know anyone who does not advocate large suckers to start with; and for what reason? Simply that he may have large plants and consequently large fruit. Mr. Ward, of Bishop Stortford, who has on many occasions exhibited some of the largest and heaviest Pines on record, believes only in suckers of giant dimensions; his plants are of proportionate size, and his Queens—to take them as an example—used to attain a weight of 6 pounds. Do we not also find the strongest growing varieties invariably producing the largest fruit—the Smooth Cayenne is more robust than the Queen, and yields proportionately heavier fruit; the Providence is a stronger grower than either and produces the largest fruit of all, and with the least trouble. It may be better for market purposes to grow more plants and have a greater number of fruits of moderate size, but let no aspirant in Pine growing get hold of the fallacy that there should be a limit to the size and vigour of his plants, provided he can get them thoroughly matured. As to the room required for Pines in the bed, I agree with your correspondent that 2 feet is ample in houses that are as light as day, to which probably his experience has hitherto been confined; but in old houses with narrow panes and sashes, or where Vines are grown overhead—conditions under which very many Pines are still cultivated—I am afraid he would find it necessary to modify his opinions considerably if he wished to get vigour enough to furnish 5 pound fruit.

A PINE GROWER.

Cherry Trees Killed by Sunstroke.—A paragraph in a Chicago journal gives an account by an eye-witness of the destruction of two Cherry trees by sunstroke. The owner, a Mr. Viesen, was standing near to them at the time (3 p.m.), when he suddenly heard a noise, which he compares to the splitting of wood. Looking in the direction of the sound, he perceived the bark of the two Cherry trees peeling off in a rapid and curious manner. The peeling commenced at the tops of the branches, and rapidly curling downwards, almost immediately stripped both branches and trunks, to the surface of the ground. The aspect of the trees was similar to that of trees stripped by lightning; foliage, bark, and fruit were cleanly peeled off, and lay in a crumpled mass at the foot of each tree, the process of scarification having been completed in the brief space of three or four seconds. It is scarcely necessary to add, that the wood appeared as scorched and dead, as though the destructive element had been that of the electric fluid of lightning, and the leaves and bark were as scorched and withered.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Plum Trees Gumming: F. H. Plum trees are very liable to gumming after having been severely pruned, or having been transplanted when growing freely. Prune away the worst affected parts in winter. The healthy shoots will soon fill up the place of those removed.

Transplanting Large Plum Trees.—I am thinking of transplanting several Plums, &c., that I value highly, and shall be obliged by your telling me the best time, and if I should cut them back.—H. W. [Do it in October. Except the tops are very large and want pruning, you need not cut back, or but little. In moving, trace out and preserve all the roots you possibly can.—W. M.]

The Trebbiano Grape.—I quite agree with your correspondent "B. J." (see p. 220) as to the merits of this Grape. "B. J." speaks of it as a late Grape, but I go further, and say of all white Grapes for pot culture the Trebbiano is by far the best. I have exhibited noble bunches of it at Stamford, weighing 4 lbs. each, finely coloured, of the best possible shape, not over large in berry, and of good flavour, all cut from pots; and I have just now some fine canes of it in pots for early forcing. In fact, so much is the variety in question thought of by both my employer and myself, that I would not be without it on any consideration.—R. GILBERT, *Gardener to the Marquis of Exeter, Barchley, Stamford.*

THE FLOWER GARDEN.

THE ANEMONE-LEAVED CRANE'S-BILL.

(GERANIUM ANEMONEFOLIUM.)

THIS is one of those plants which some years ago had all but disappeared from cultivation. The wheel of fashion, like the wheel of fortune, is, however, in continuous revolution, and once more this, like many other long neglected plants, crops up again. Knowing how fickle and inconstant are fashion's fancies, and also satisfied, as I am, that this *Geranium* possesses claims for general cultivation of a really substantial character, I willingly supplement the very truthful and admirable figure herewith given, with a few descriptive remarks. Introduced in the latter part of the last century from the Canary Islands, it received its appropriate specific title at the hands of Willdenow, and, along with *Geranium canariense*, constitutes a very distinct little group, holding a position intermediate between the two genera *Pelargonium* and *Geranium*, to both of which it has been, at various times, indiscriminately referred. This species, though sometimes called a biennial, is, with a little care, a long lived, somewhat shrubby, plant, inclined, after a series of years, to become long in the stem, hence it is desirable to have an occasional succession of young plants, as it does not stand "heading back" the same as the more truly woody *Pelargoniums*. It reaches its most perfect condition when its stem acquires a height of about 12 or 15 inches. The space below thus given enables the leaves, which have a tendency to reflex downwards, to arrange themselves with a grace, regularity, and lightness, that cannot be attained when the leaf development takes place from the surface of the ground. As an indoor spring decorative plant, the Anemone-leaved *Geranium* should never be lost sight of; its beautifully-divided palmate foliage of shiny green, and the mass of flower-stems rising above the same, covered with a succession of rosy-red star-like blossoms, give the plant an attractive appearance, perhaps all the more powerful from the charming simplicity of the flowers themselves. When planted out in the flower garden, it should not be the sole occupant of a bed to itself, as its appearance is too sombre; enlivened however, with the bright colouring of the variegated *Abutilon*, and margined with *Gnaphalium lanatum*, a few of whose vigorous shoots may be allowed to run irregularly amongst the leaves below, its beauty of form is wonderfully enhanced. In this way I have seen a bed present a very effective and novel appearance. If the ground be rich, due allowance must be made to keep the plants well apart, as, when thus turned out, with its roots ranging beyond the restrictive limits of the pot, it is not unusual for it to form leaves fully 12 inches across, on foot-stalks of about an equal, or even greater, length. In a young state, the other species, *Geranium canariense*, bears so close a resemblance to *Anemonefolium*, that it is almost impossible to recognise any distinctive characters; but, when in bloom, the difficulty vanishes, as, whereas the latter has smooth stalks

throughout the entire inflorescence, the former is clothed with the most exquisite purplish hairs, each one tipped with a tiny globule of secreted, or, perhaps I ought to say, excreted moisture. So dense and conspicuous is this arrangement of hairs, that it gives a decided character to the plant, and at once distinguishes it from its otherwise closely-allied species; added to this, the petals of the flower are broader, and, in place of a rosy-red colour, they have a lovely violet or purplish tint superadded—a combination of colours not frequently met with. Both these species seed freely, and by this means are readily propagated; so elastic, however, are the indurated styles that, unless carefully watched, the seeds are apt to distribute themselves far and wide long before the cultivator has any suspicion that they are matured.

JAS. C. NIVEN.

Hull Botanic Gardens.

ROSES ON THEIR OWN ROOTS.

TO anyone acquainted with the immense number of Roses propagated every year by budding and grafting, the question necessarily arises, what becomes of them all? Granted that each year growers of Roses increase, yet even these, numerous as they are, will not account for the incalculable quantities that are produced. What, therefore, becomes of them? Doubtless, great numbers perish, and that, from various causes, the most destructive of which are bad treatment and unsuitable soil for Roses on other than their own roots. The enormous number raised by budding and grafting has in some measure led to the impression among people generally, that these methods of raising Roses are the best; and, that advantages belong to the budding and grafting system, under certain cir-

cumstances, must be admitted, inasmuch, as by these processes they can be increased much faster than they could be on their own roots, which, in the case of new sorts, doubtless, is an advantage; and, for them, there can be no possible objection to this method of Rose propagation. But here I am of opinion it ought, in a great measure, to cease, and give place to the far better, more effective, and more natural system of growing them on their own roots, which, for general purposes, is superior to any other method. There are some that are naturally weak in constitution, and that are consequently better to manage on a stock somewhat stronger; yet even thus treated, they do not always succeed; seeing, however, that we have a multiplicity of varieties of almost every shade, the total discarding of these delicate sorts would be no loss to any except those who exhibit for competition. It is generally admitted, I believe, that the best flowers are produced from the first season's bloom after budding. I am not, however, looking at the subject from an exhibitor's point of view, but from that of the thousands who grow Roses as decorative plants only, and, for this class of growers, with few exceptions, they are in every way preferable on their own roots. There are, no doubt, places in any garden where a good standard Rose looks well and is in a proper position; but a bed or a

The Anemone-leaved Crane's-bill (*Geranium anemonefolium*).

Rose-garden of standards, compared with a similar bed occupied by Roses bush-fashion on their own roots, is a very poor affair. A bed of standard Roses (apart from the peculiar associations connected with Roses above all other flowers, and their individual beauty and fragrance) is not an arrangement in keeping with good taste, and, when not in bloom, is absolutely intolerable, holding, as it usually does, a position in the best and most conspicuous part of a well-kept garden. This arises from various causes: first, the shape of the plants, with their naked stems; their unsightly appearance through the winter; and the sight through the summer of the ground covered with mulching manure, or with the always apparent efforts when attempting to hide it by Mignonette or other plants that are used for the purpose, and which have never any business there at all, on account of their extracting so much from the soil that ought to be wholly in the possession of the Roses. As opposed to this, a bed of Roses on their own roots is a most charming object, and even in the winter, when denuded of leaves, can be made to look unobjectionable. Roses on their own roots possess many advantages. The first is, there are not the unsightly gaps consequent upon the numbers of standards that lag behind, and have a sickly appearance, and which, from their position, stand most objectionably prominent. In a bed of Roses on their own roots, those which do not succeed are comparatively few, if common care is taken in selecting kinds that are not delicate growers. Hence, mulchings can be applied without being so apparent; in fact, they can be all but hid by the plants they are to benefit. The best and most effective way of treating Roses grown on this method is to peg the shoots down. Let us take a bed or garden of these that has been some time planted and treated in the ordinary way, and on which it is intended to try the pegging-down system; the plants will contain some old wood, a portion of which may have existed for years, and numbers of strong current season's shoots from the collar, or near it. In spring, when pruning time comes, cut the whole of the old wood out right down to the bottom, leaving nothing but the young vigorous shoots in numbers proportionate to the strength of the plants. If very strong, eight or ten may be left, if weaker, four or six; these may be shortened back to from 3 to 4 feet, according to the distance the plants stand apart. Procure some stout hooked sticks a foot long, so that they may have good hold in the ground; with one of these peg each shoot down evenly all round from the collar, bringing them down to within an inch or two of the ground, having previously given a good mulching with manure; they will, thus treated, break at almost every eye, and flower profusely if they are strong and otherwise in good condition. This bringing down all the shoots in a horizontal position has the effect of causing the plants to break up from the bottom much stronger than they would under other treatment, and many of these shoots will flower in the autumn after the beauty of the pegged-down portion is over. I have from these current season's growths had much better blooms, and in greater numbers, than ever I was able to get from the second crop produced by standards. If strong and in good condition, the pegged-down shoots will produce a second lot of flowers. In the winter, when the time arrives for digging the ground and putting in manure, cut out all the shoots that are pegged close from where they spring, so as to give an opportunity for the work being done in the spring, as before—mulching, pruning, and pegging down the young shoots. This method of Rose growing, I may observe, is anything but new, and the wonder is that it has not become more universal than it is amongst those who grow Roses for general purposes, a circumstance which can only be accounted for by the present system of growing them as standards having become so popular, the great bane of which, looked at from a purely cultural point of view, is their continuous disposition to throw up suckers, which, even when removed as soon as they appear above ground, greatly weaken the plants, and are a source of continual trouble; while, as regards Roses on their own roots the reverse is the case, every shoot of which, coming up from the bottom, is an evidence of strength and a future advantage. Then, again, all the tender Tea varieties, that are so often killed, even in ordinary winters—if cut down to the ground by frost, will push up strongly from the root, and flower later in

the season. There are winters that now and then occur, although they may be at considerable intervals, that forcibly remind us of their effects. Who has forgotten the wholesale destruction in the winter of 1860-61, when nineteen-twentieths of the standard Roses throughout the kingdom were killed, the few that escaped being mostly such as had been moved the autumn previous? Then three-fourths of the growers in the country avowed their intention henceforth to grow them on their own roots; yet, as time wore on, they gradually relapsed into the old system.

Were there any difficulty in striking Roses from cuttings, and, consequently, growing them under the best and most satisfactory conditions, the case would be different. Certainly, as I have already remarked, they cannot be produced so quickly or in such numbers by this method as by budding; but, for the thousands of amateurs who propagate their own Roses and who take a pleasure in such occupation, they would be the most satisfactory on their own roots. There are several methods employed in striking Roses. The first is within the reach of everyone who has sufficient ground to grow them. It is simply to take off with a heel moderate-sized shoots, neither too weak nor too strong and gross; these should be procured about the beginning of October. A nice piece of ground that is not wet, in a somewhat sheltered situation, but not at the shady side of a wall, should be chosen for them; dig it over, and, if of a heavy and adhesive nature, get some lighter loam and sand, and mix the whole together, elevating it a little. In this insert the cuttings, about 4 inches asunder every way, give them a good watering and put a temporary frame round them made of boards 6 or 8 inches deep; on this nail some wire netting to keep anything from disturbing them, and, when severe frost comes, throw some litter over them. The wire, if supported with a few pieces of timber, will carry the litter without letting it absolutely rest upon the cuttings. Here they must remain, and in spring the greater portion will root and commence to grow, when they should be removed to a nursery bed of good rich soil, planting them 15 inches asunder. If kept clean and free from insects through the summer, they will make considerable progress. They may remain here for another season, when they will be good plants, and in the autumn may be transferred to the beds they are intended to occupy.

Another and much quicker method, that can be followed by those who have the convenience of heated pits or a greenhouse, is to take cuttings off earlier in the season—the second growth that pushes after the principal flowering, as soon as it gets sufficiently hardened, which will depend upon the season being late or early—generally about the middle of August. The shoots for this should be about half ripe, taken off with a heel, have their bottom leaves stripped off, and be inserted six or eight in 48-pots of sandy loam, giving plenty of water, and placing them in a cold frame for three weeks or a month, keeping the soil quite moist; at the expiration of this time they will have become well callused, when they must be removed to a gentle hot-bed, where they will root directly. On no account must they be placed in heat before this callusing process has taken place; otherwise not one in a dozen will strike. When they have pushed an inch or two, they must be potted off singly into 3-inch pots, in good soil, and replaced in a temperature of 50°, with a moderate amount of air and a growing atmosphere. Here they will gain strength, and must be encouraged for some some weeks to make growth, after which they may be removed to a house or pit for the winter with an ordinary greenhouse temperature of from 35° to 45°, the object being not to allow growth to become quite stagnant. From the small size of the plants, a large number may be accommodated in a little space. In the spring, as soon as they begin to move, shift them into pots a size larger, and place them in a pit or frame, where they can be so treated as to induce them to grow. Gradually inure them to the air, and in the beginning of May plant them out in good rich soil in an open situation; by this means a season's growth will be gained over what may be termed the dormant cutting system. All they require is keeping free from aphides and weeds, and giving a sufficient supply of water in dry weather. In the autumn they may either be removed to the ground they are ultimately to occupy, or they may be allowed to remain another season; all that is necessary is not

to neglect them in their preparatory stages. Some there are who may be disposed to say that this involves considerable attention and room under glass; yet the same individuals have never most likely considered that it is no more than is required for ordinary bedding plants, that only last for a few months at their best, while the plants in question will last for a number of years and go on improving. In the case of such kinds that are already possessed in strong plants grown in the way under consideration, and which it is desirable to increase, this can be done well and expeditiously by—in the spring when they are pegged down—removing an inch or two of soil, and sinking into it about 6 inches of the points of some four or five of the shoots from each plant, well securing them with the hooked sticks; these will push up strong growths, rooting freely and making large plants the first season, that in the autumn—about the end of September—only require severing from the old plant and transferring to where they are to remain; they will flower well the succeeding summer, and the year following will make plants as large as ever they will be required. Any one having Roses grown in this way, let the number be large or small, can, by this system of layering, quadruple his stock every year, without in any way interfering with the flowering of the plants. There is yet another advantage—that in some places where the ordinary stocks, Dog Rose or Manetti, will not thrive, Roses on their own roots, if free-growing varieties are selected, will succeed. Therefore, my advice to all lovers of Roses is—grow them on their own roots. T. BAINES.

DRAPING DEAD WALLS.

Dead walls are the nightmare of many a suburban garden. However perfect the latter, the walls, which of necessity bound it, in most cases mar it more or less. Draped with Roses, Jasmines, and Honeysuckles, the bricks and mortar are hidden, but the straight sharply-defined lines remain. Got rid, by any means, of the straightness, and substitute curved lines of beauty, or irregular lines, and picturesque, and the most objectionable features of walls vanish. We have long been advocates for breaking up the flatness of the ground lines of gardens and partially destroying the tiresome monotony of straight walls with mounds of earth. It is astonishing how much can be done by such means, and by clothing the mounds by judicious planting. By the influence of raised base lines, and their skilful furnishing with trees, shrubs, and plants, the wall lines may be almost totally concealed, and the sharp corners at least rounded off with vegetation. The stiffness of the visible portions of the walls may be relieved by a loose style of training. Jasmines, Honeysuckles, Clematises, Virginian Creepers, Banksian and other Roses should be backed up against rather than closely trained to walls. Ivies, likewise, are quite different plants when left to roam very much at their own sweet will. The Japanese Honeysuckle is also one of the most suitable plants for this free style of furnishing. Its golden shoots stream down in profusion, covering the bare crown or face of walls as golden ringlets do the shoulders of childhood. Virginian Creepers, again, and the Wistaria are admirably adapted to this loose style of training, also all the large leaved kinds of Aristolochia and the ever welcome green of Figs and Vines. By allowing a free summer growth, the stiffness of the boundary walls of villa gardens may be hidden behind a massive screen of pendent shoots and beautiful foliage. This freedom is, as a rule, the one thing that villa gardeners seem intent on destroying. Close spurring and a smooth straight surface are the only modes of pruning and training adapted by almost the whole race of professional wall dressers, who go about with knives and shears and ties or nails seeking to fasten up or destroy each free and graceful growth they can find on the face of the wall. They have but one idea of cropping—the convict model—all round and all bare alike. If walls are to be gracefully draped, they must first be emancipated from the hard and fast lines of the jobbing gardener. The lady who can attire herself with elegance, has received the best training for the draping of her garden walls. To prevent mistakes, however, it is needful to bear in mind a distinction. To trim a dress means to add a new grace to it; to trim a wall, as generally understood, is to slash all grace off it. But after all that can be done by the raising of banks of earth and planting them with skill, and the furnishing of the walls with a free growth of suitable plants, the chances are that pieces of wall, straight and bare, may still be visible here and there. In such cases, and also where difficulties may occur in the way of adopting the foregoing methods of adornment, or in conjunction with them, the wall itself may be operated on. The best materials for this purpose are lumps of stone, burrs, or spoilt bricks, clinkers dipped in cement, or even the refuse of smelting furnaces; these, in considerable masses, may

be used along with old roots or pollard stumps on the crowns and sides of earth mounds so as to give greater variety of outline, and afford root runs at once suitable and picturesque for various creeping or other plants, and for Ferns and succulents, both excellent for the draping of walls earth-cased or otherwise. Mineral or vegetable debris, such as wood or cork, may also be placed on the surface of the walls in such a manner as to form irregular outlines and furnish pockets, recesses, and crevices full of suitable soil for the nourishment of such plants as Ferns, succulents, and drooping or dwarf Alpines or other plants. Perhaps hardly any more useful plants could be named than *Linaria Cymbalaria*, *Lysimachia Nummularia*, *Phlox subulata*, *Campanula rotundifolia*, *C. garganica*, *Lithospermum prostratum*, *Potentilla alpestris*, *Antirrhinum rupestre*, *Veronica prostrata*, *Saxifraga sarmentosa*, *Helianthemum*, all the slender varieties, &c., &c. Again, Ferns alone would drape a wall, almost any wall, to perfection; and, fortunately, the cold northern or eastern, or any shady slimy wall, where nothing else would thrive, is just the favoured haunt of Ferns. With sufficient peat soil to root in, and the garden engine and watering pot given overhead now and then, they can be made to beautify and adorn any wall, however bleak and bare.—*Villa Gardener*.

Momordica Charantia.—This is a widely spread East Indian Cucurbitaceous annual, which has bright yellow oblong fruits, from 4 to 8 inches long, tapering to both ends, and covered all over with little wart-like protuberances, some irregular and others in lines, along which they split when ripe. The flowers are too small to be ornamental; the chief attraction therefore is the fruit, which, when fully ripe, splits up into three parts, and has the appearance of a bloom with large thick petals. The inside is wholly covered with a deep red pulpy matter, which forms a fine contrast with the yellow exterior. The seeds imbedded in the pulp look as if carved. The plant generally takes from two to three months to mature its fruit from the time when the seeds are sown, and then it keeps in bearing condition for some months. The seeds should be sown in a light soil, and assisted to germinate with a little bottom heat. When the young plants are large enough to handle, they may either be planted out and trained on a trellis, or grown on in pots, and staked into a balloon, or pyramidal shape, or any form desired. As it is a gross feeder, a rich soil suits it best, and the fruit is improved in size by an occasional application of liquid manure.—*J. Muir, Clovenfords*.

New Bedding Violas.—I heartily recommend the three following forms—*Viola cornuta Sensation*, *Viola cornuta Admiration*, and *Viola cornuta Purple Prince*. The former is, perhaps, the earliest of these examples of "new blood," the second and third, the second especially, being among the most telling of all summer bedding plants, especially when mixed with any of the white variegated-leaved *Pelargoniums*, such as *Bijon*, *Flower of Spring*, &c. As even a preferable companion to these, I may instance the old *Mangles Variegated Pelargonium*, amongst which I have some of these Violas growing, and the effect is certainly heightened, as the Violas seem to show up better from amidst the more procumbent stems and the smaller blooms of this kind. Then, again, as early spring plants, for blooming along with the Daisies, *Yellow Cliveden Pansies*, *Silenes*, *Primroses*, *Polyanthuses*, and *Tulips*, they are unapproachable. I have also seen them introduced in circular masses in front of young shrubberies, thus forming a continuous link in the chain of display, brilliant in their effect, of which similarly-coloured *Crocuses* give the foretaste, but which these Violas certainly beat, both in respect of colour and of distant effect.—*WILLIAM EARLEY, Valentines*.

Autumn Meadow Saffron (*Colchicum*).—It would hardly be possible for those who have not seen the leading varieties of *Colchicum* in bloom to conceive how decorative they are in the flower garden, and how valuable for prolonging the succession of flowers. In September and October, and even in November, the display produced by a good collection of *Colchicums* proves most attractive. Some of the varieties have beautifully chequered flowers, and most of them are so floriferous as to cover the ground with a sheet of blossom, and as the leaves do not appear till spring, at a little distance the effect is peculiar, there being nothing but colour. The best position in the flower garden for the *Colchicum* is the mixed flower and shrubbery border, and the woodland walks, but its accommodating habits readily admit of its utilisation in flower beds. In beds of dwarf plants, or where the *Geraniums* are not crowded together, the roots of the *Colchicum*, lifted when at rest, may be planted, making holes with a common dibber all over the flower bed, planting a *Colchicum* in each hole, and covering it with soil. These roots will throw up large masses of *Crocus*-like blossoms just as the summer flowers are dying off, and yield a most pleasing and distinct effect to the summer decoration. *C. byzantinum*, with its rose-coloured flowers; *C. variegatum*, with its beautifully chequered

blossoms; and *C. autumnale*, with its rose-purple flowers; and the purple, the variegated, and the pure white double kinds, may be intermingled or arranged separately in distinct beds. Thus, these beautiful and hardy blossoms of autumn will prove as useful in the ordinary flower garden as in the choice mixed border, or hardy bulb garden.—PETER BARK.

Hardy Aquatics.—Will you kindly furnish me with the names of a dozen hardy Aquatics? I want them both for the middle and edges of a newly-made ornamental lake, and I should also like to know where collections of these plants are to be seen?—Z. [For the central portion of your lake select such plants as the white Water-Lily (*Nymphaea alba*), yellow Water-Lily (*Nuphar lutea*), *Villarsia nymphaeoides*, the Water-Violet (*Hottonia palustris*), Bog-Bean (*Menyanthes trifoliata*), and the Floating Aponogeton (*A. distachyon*) and its varieties. For the margins nothing can surpass *Cyperus longus*, the gracefully-pendent *Carex pendula*, the white-spathed North American Calla (*C. palustris*), the Marsh Flag (*Iris pseudacorus*), the Typhas, and the handsome-flowering Rush *Botanus umbellatus*. The best collections round London, with which we are acquainted, are those at Kew, the Wellington Nurseries, St. John's Wood; the Hale Farm Nursery, Tottenham; and Parker's and Rollisson's Nurseries, at Tooting. Good collections of them are likewise grown in various provincial Botanic Gardens, notably at Oxford and Edinburgh.]

The New Hardy Crinum.—With reference to this interesting plant, Dr. Hooker remarks in the *Botanical Magazine*—A hardy Crinum is a rarity in English gardens, and except the beautiful *C. capense*, I know no other but this now in open air cultivation; and beautiful as *C. capense* is, it is far exceeded in size, foliage, and colour by the subject now under notice. Crinum Moorei was introduced into the Glasnevin Gardens in 1863, by Mr. Webb, a friend of Dr. Moore's, who had served on the commissariat staff of our army in South Africa, and had brought the seeds from the interior—as Dr. Moore thinks—of Natal. During the last five years the specimen from which the drawing in the *Magazine* was made has been planted in a border fronting the conservatory range at Glasnevin, without getting the slightest protection, flowering sometimes in autumn, and at other times in spring. The leaves are cut up in the winter, but the bulbs are not seriously hurt, and soon recover themselves, when they push out a fresh set of their broad peculiarly-ribbed leaves, 18 to 20 inches long. The bulb is remarkably long, sometimes reaching 18 inches. A closely allied species to this is the *C. Colensoi*, of Natal, which will shortly be figured, which has also broad leaves and a long bulb, but the perianth-tube is much longer, and the flower smaller, with a narrower pale limb; it has been flowered by Mr. Ball and others, and may, we hope, also prove hardy.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

The Fruiting Duckweed (*Nertera depressa*).—Would you kindly say if *Nertera depressa* is an Alpine plant or not, and oblige J. C. & Sons, Aberdeen. [The Fruiting Duckweed is a native of New Zealand and the Andes of South America, and succeeds perfectly under the treatment usually given to Alpine plants. It grows in the open air, and should have a moist spot in the rock-garden.]

The Ivy Harebell on a Lawn.—Mr. Dawson (see p. 221) says, "few gardens can supply a turf-moss corner for this Campanula." It spreads freely on our lawn; and, as one portion is, in consequence, left unknown in July, we have a sheet of blue flowers, than which nothing can be more lovely. It spreads rapidly; as also *Scilla europaea*, which likewise makes a lovely hanging-basket in the greenhouse, falling down fully 2 feet from the pot or basket.—E. L. R., *Yorkshire*.

Hardy August and September Blooming Plants.—"Simon" should have no difficulty in keeping his garden aglow through the autumn with hardy flowers. In addition to those named in your last number, he may have *Rudbeckia* in variety (especially *hirta*), *Eurotia Fraseri*, *Chelone obliqua*, *Dracopis speciosum*, *Tritoma* in variety, *Tritoma aurea*, late *Phloxes*, *Sparaxis pulcherrima* (in great beauty just now), *Platycodon autumnale*, *Verbena venosa* (a beautiful purple), *Aconitum autumnale* (a brilliant blue), and, for the front line, *Cyclamen hederifolium*.—S. G. S. G. S. G. S.

Miniature Tulips.—Last season, after bedding out our spring bulbs, there chanced to be two or three dozen Tulips over and above our requirements. These were thrust into a small bed at the bottom of the garden, and left without water or other attention. When blooming time arrived, they turned out to be miniature Tulips about the size of large Crocuses, while their companions, viz., those which had been properly planted and cared for in show beds, were of the full and usual size. On one of the dwarfs being lifted, the root was found to be loosely surrounded by dry leaves.—F. H. B., *Cumbria* & N.

Roses not Opening.—I have a young Rose tree (General Jacquemont) which obstinately refuses to expand a large number of its buds. They grow until they become large red lumps, at which stage they remain. The petals are all there, no doubt, as I have tried the experiment of forcibly unrolling them, and have produced, in some instances, a very fair flower. Can you point out the cause and the remedy?—J. W. [Drought has doubtless played an important part in this case after the buds had been formed. Clustered flowering Roses frequently behave in that way in dry seasons after the middle or leading bud has expanded. Water, or even liquid-manure, should be given if the trees are healthy, so as to avail themselves of it; and an occasional syringing over the head of the tree will also be found to be beneficial. If all this has been done, then the soil must be changed, for Roses will not open in worn out soils. Get good fresh loam, and re-plant in November.—H. G.]

THE FALL OF THE LEAF.

BY HARLAND COULTAS.

THE phenomenon of the "fall of the leaf," common as it is, is very difficult to explain satisfactorily. The following are the facts, so far as we understand them, which are exceedingly interesting and instructive. It seems that Nature begins the provision for separation almost as soon as the leaf is born in spring. When first put forth into the atmosphere, the stalk of the leaf, supposing one to be present, is continuous with the stem. As the leaf and its stem grow, however, an interruption between their tissues (fibrous and cellular) takes place at the base of the leaf-stalk, by means of which a more or less complete articulation or joint is gradually and ultimately formed. This articulation is produced by the continuation of the growth of the stem after the leaf has attained its full growth, which it generally does in a few weeks. The growth of the leaf being completed, the base of its petiole, or foot-stalk, is no longer able to adapt itself to the increasing diameter of the stem, and a fracture between that base and the stem necessarily ensues; the excision advances from without inwards, until it finally reaches the bundles of woody fibre, which form the main support of the leaf. Whilst, however, Nature is forming a wound, she is at the same time making provision to heal the same; for the cuticle or epidermis of the stem is seen to grow over the surface of the scar, so that, when the leaf is detached, the tree does not suffer from the effects of an open wound. The provision for separation being thus completed, the leaf is parted from the stem by the growth of the bud at the base, the force of the wind, or even by its own weight. Therefore, as soon as the glorious colours of the autumn leaves begin to fade, this provision for separation is completed, and the winds sing their death-dirge as they carry them away from their summer's home on the branches of the trees, and scatter them in countless numbers upon the ground. The fall of the leaf is, therefore, the result of a regular vital process, which commences with the first formation of the leaf, and is only completed when it is no longer useful to the tree. There is no denying, however, that the frosts of autumn, by suddenly contracting the tissues at the base of the leaf-stalk, accelerate the fall of the leaves. All must have noticed, on a frosty morning in autumn, that the slightest breath of air moving amongst the decayed and dying leaves will bring them in complete showers from the trees to the ground. The leaves of the Beech, Hornbeam, and Oak, die in autumn, but frequently remain attached to these trees through the winter months, provided that the trees are not so situated as to be exposed to violent winds. Such leaves, when examined, will be found to be continuous with the stem; and, therefore, without that articulation or joint which so naturally assists in the separation of the leaf from the tree. These dead leaves fall off when the new leaves are put forth in spring; they are, in fact, pushed off by the expansion of the stem when the growth of the season commences. The leaves of evergreen trees and shrubs, and of Coniferous trees, as the Pine and Fir, do not fall in autumn but in spring, when the growth of the season is taking place; and, as this annual leaf-fall is only partial, consisting of one-half or one-third at a time, there is always a sufficient number of leaves left on such trees to keep them clothed with perpetual verdure. Hence it is that their foliage consists of leaves which have been attached to the stem from one to three or five successive years.

Who has not been struck with the beauty of the woods in autumn, when the leaves change their colour, and from one dull uniform green become tinted with every variety of hue? The beauty of the fading flowers appears to have been transferred to the leaves, as if Nature would rival, at the close of the growing season, those charms with which she adorned herself at its commencement. This last observation is especially applicable to the autumnal tints of the forests of North America which are much more vivid and picturesque than those with which autumn colours an English landscape; in fact, an autumn in Virginia, Maryland, or Pennsylvania, is a chapter of the beauty of the world for which the old Continents have no parallel. The birth of this beauty is as sudden as its duration is transient. A single night's frost, and the uniform green of the summer woods is succeeded by the colours of autumn—this in all their rich and inimitable shades. The forests of North

THE FALL OF THE LEAF.

America consist principally of Oak, Hickory, Beech, Chestnut, Maple, Sour Gum, Sassafras, and Dogwood, intermingled with evergreens, such as the different varieties of American Holly, Pines, Fir, and Juniper. There is, therefore, quite a variety of deciduous-leaved trees, and each of them has a regular series of colours through which its leaves pass, after they have received the death-stroke of the frost. The solar spectrum is exhausted in this fantastic display of colours. A single tree sometimes stands a pillar of fire or a glittering cloud of gold and purple; while, again, the crimson blood dye is succeeded by a tree which has taken its hue from the gaudy yellow of the Nasturtium cups or the "dolphin's back of gold." Soon, too soon, the bright colours fade! A few hours are sometimes sufficient to mar all this loveliness. A change in the temperature or moisture of the air and the beauty is gone. It has vanished like the rainbow painted on the storm cloud. The bright and varied colourings are succeeded by the dull and uniform russet hue of the dead and withered leaf—the dark brown into which it passes, ere mouldering into dust and death.

The following is a list of some of the deciduous-leaved trees, common in the forests of the Northern States, whose leaves colour beautifully in autumn:—

Tulip Tree (<i>Liriodendron Tulipifera</i>)	Sugar or Rock Maple (<i>A. saccharinum</i>)
Smooth Sumach (<i>Rhus glabra</i>)	Red or Swamp Maple (<i>A. rubrum</i>)
Virginian Creeper or American Ivy (<i>Ampelopsis quinquefolia</i>)	Flowering Dogwood (<i>Cornus florida</i>)
Silver Maple (<i>Acer dasycarpum</i>)	Sour Gum (<i>Nyssa multiflora</i>)
Striped Maple (<i>A. Pennsylvanicum</i>)	Red Bay (<i>Persea carolinensis</i>)
Mountain Maple (<i>A. spicatum</i>)	Sassafras (<i>Sassafras officinale</i>)
	Spice-bush (<i>Laurus Benzoin</i>)

THE OAK FAMILY.

Scarlet Oak (<i>Quercus coccinea</i>)	Water Oak (<i>Q. aquatica</i>)
Red Oak (<i>Q. rubra</i>)	Black Jack (<i>Q. nigra</i>)
Shingle Oak (<i>Q. imbricaria</i>)	Turkey Oak (<i>Q. Catesbei</i>)
High-ground Willow-Oak (<i>Q. cinerea</i>)	Black Oak (<i>Q. tinctoria</i>)
Live Oak (<i>Q. virens</i>)	Chinquapin Oak (<i>Q. Prinoides</i>)

The foliage of all the Maples changes colour in autumn, the prevailing hues being yellow and different shades of red. In the Red Maple (*Acer rubrum*) the entire surface of the leaf is coloured red, and from this circumstance, the specific character of the tree is taken. The Scarlet and Red Oaks are named especially in reference to the colour of their leaves, which turn to a light red or bright scarlet with the first frosts of autumn. The crimson leaves of the last species, when it abounds, impart a magnificent appearance to the American woods in autumn, blending with the yellow of the Maples, the light brown of the Black Oaks, and the evergreen foliage of the Live Oak, Chinquapin and Turkey Oak.

For the following list of trees remarkable for their autumn-tinted foliage, we are indebted to Messrs. Osborn, of Fulham:—

<i>Ampelopsis hederacea</i>	<i>Crataegus flava</i>
<i>Amelanchier vulgaris</i>	" <i>lobata</i>
<i>Carpinus americana</i>	" <i>trilobata</i>
<i>Crataegus coccinea</i>	" <i>cordata</i>
" <i>corallina</i>	" <i>Azardus maroccana</i>
" <i>maxima</i>	" <i>Aronia</i>
" <i>acerifolia</i>	" <i>orientalis</i>
" <i>glandulosa</i>	" <i>sanguinea</i>
" <i>subvillosa</i>	" <i>tanacetifolia glabra</i>
" <i>punctata rubra</i>	<i>Diervilla canadensis</i>
" <i>stricta</i>	<i>Fraxinus discolor</i>
" <i>brevispina</i>	" <i>platycarpa</i>
" <i>aurea</i>	<i>Hamelis virginica</i>

Remedy for Insect Stings.—It is said that thirty or forty grains of quicklime dissolved in water is a thorough cure for the stings of insects, and far superior to ammonia or any other alkali.

THE ARBORETUM.

LILACS.

LILACS are indigenous to a comparatively limited area in Europe, but they have a wide range in Asia; and, in addition to several distinct species, for the most part well-known and widely-cultivated, our collections have been from time to time enriched by the accession of a large number of splendid varieties, obtained either by hybridising or by selection from garden sports. Some of the sorts are useful for early forcing, and are invaluable for the winter and early spring decoration of the conservatory. The stronger-growing species form symmetrical bushy-headed small trees, when grown with a single stem as standards, the root-suckers (which, particularly in the early stages of their growth, they throw up in great abundance) being regularly removed, and the upper branches being carefully regulated by judicious stopping or pruning, an operation which should be performed as soon as possible after the fall of the leaf in autumn. There are few garden soils in which Lilacs will not grow, and even thrive, though they succeed all the better in such as are deep and rich, with a cool sub-soil; and an occasional moderate allowance of well-rotted manure, pointed in among the roots, is always acceptable.

Syringa vulgaris (the common Lilac) is recorded as indigenous to Hungary and Persia, and has been cultivated in British gardens since 1597. It is naturally a many-stemmed broad bush, varying in height from 15 to 25 feet, according to soil and situation; but when trained as a standard, it makes an extremely handsome lawn or park plant, producing its grand panicles of fragrant lilac flowers about the middle of May, in wonderful profusion. This fine old-fashioned plant, so familiar to all of us, adorning alike the parks of the rich and the gardens of the poor, and forming as it does such a prominent feature in our woodlands, requires no eulogy with the view of commending it to the attention of the decorative planter; its sterling merits render its presence indispensable in every collection or arrangement of ornamental shrubs. As it grows freely, and rarely fails to flower, even amid the disadvantages of dust and smoke in towns, it should never be overlooked in making a selection for planting squares and street gardens. Of this species there are a large number of interesting varieties, of which the following may be noted as very distinct, and, both as regards foliage and flowers, no less beautiful than the parent:—*Alba*, the well-known old white-flowered Lilac; *Noisetiana*, also white, but with larger panicles; *cærulea*, flowers deep blue; *violacea*, a kind with violet flowers; *Charles X.*, purple, panicles very large; *Philemon*, lavender-coloured; *Dr. Lindley*, rich purple, panicles very large; *Triomphe de Orleans*, pinkish purple; *rubra insignis*, dark red; *Duchesse de Nemours*, pale blue, panicles and flowers very large.

S. persica (the Persian Lilac), indigenous to Persia, from whence it was first introduced in 1610. In this country it is perfectly hardy, and forms a neat dwarf bush, of from 4 to 6 feet in height, with numerous slender branches, its panicles of pale-purple sweetly-scented flowers coming out in May or June, in such abundance as almost to hide the foliage. The leaves are smaller than those of any of the other species, somewhat lanceolate in form, and of a dark green colour. This pretty little plant is invaluable for small gardens or shrubberies, growing vigorously in any kind of good garden soil, and in any situation in which a shrub could be expected to thrive; it is, moreover, one of the freest of early forcing shrubs, and forms a charming object for winter conservatory decoration. Of varieties, *alba*, with pure white flowers, and *lacinata*, with leaves more or less deeply pinnatifidly cut, are both quite as hardy and easily cultivated as the parent, and well deserving of a place among the choicest of dwarf shrubs.

S. Emodi (the Himalayan Lilac) is found abundantly on the Himalayan Mountains, and was first sent home in 1836. It is a broad thickly-foliaged shrub of about 10 feet high. The leaves are larger than those of the common species, of an elliptic-oblong form, bright green above and slightly glaucous below. The flowers are light purple, produced, like those of the other species, in panicles, and usually in perfection in May. Though thriving best in a moderately sheltered situation, it is a very hardy shrub, quite distinct in appearance from the others, and ornamental enough for association with the finest of its class, forming a neat standard when properly trained, and very desirable for small lawns as a single specimen.

S. Josikæa (*Josika's Lilac*).—This is indigenous to mountains on the Rhine, and was named in compliment to a lady—the Frau Baronin Von Josika—who discovered it on the Siebenbergen Range in 1830. It forms a handsome bush of about 10 feet in height, somewhat erect in its style of growth. The flowers are of a very deep purple colour, and sparingly distributed over the long panicles. The leaves are similar in size to the common Lilac, but more lanceolate in shape, with a rough leathery texture, and a dark sombre-green colour. Though this plant neither produces its flowers in such

rich masses, or so copiously as the common Lilac and its varieties, it is nevertheless a valuable ornamental shrub, hardly enough for the most exposed situations, and so distinct in appearance, from its peculiar habit and foliage, that it produces the finest effect when contrasted with other shrubs of lighter tints in mixed borders. It thrives best in a deep, rich, and moderately damp soil.

S. rothomagensis (the Siberian, or Rouen Lilac).—As to the history of this shrub there are differences of opinion. Some writers assert that it is a native of Siberia, and a distinct species; others that it is a hybrid raised about the latter end of the last century by M. Varin, the then director of the Botanic Gardens at Rouen, the parents being *persica* and *vulgaris*. [The probabilities seem to be in favour of the latter theory, as in general appearance it is just what might be expected from the blending of the styles of growth, foliation, and flowers of the two species. In any case, the same plant is found in collections both under the name we have adopted and under that of *sibirica*. It was first introduced into our gardens in 1795, and has since been widely distributed, and is well known as one of the showiest, most beautiful, and hardiest of flowering shrubs. Though more robust in its habit of growth than *persica*, it has a general appearance suggestive of a large variety of that species, and is a grand plant either for a shrubby border, or as a close bush for a lawn specimen. It is a capital plant for early forcing—flowering abundantly when in a young state—and easily excited into growth with moderate heat.—*The Gardener*.

The Yellow Wood Cladrastis (Virgilia) tinctoria or lutea.—"This is one of the very handsomest and neatest of ornamental trees," says Dr. Gray in his "School and Field Botany;" and while all who know this tree will agree with him, it should also be added, that it is one which is almost universally omitted from lists of choice kinds. I was reminded of the words of Dr. Gray while standing in the shade of a splendid specimen of it on my lawn, which was a mere whip-handle when planted ten years ago. The Yellow-wood tree is a native of Kentucky and further south, growing on rich hill-sides, but it is also quite hardy throughout the Northern States. In the Cambridge Botanic Garden, near Boston, there is a magnificent specimen of it, planted there more than fifty years ago. When standing alone, this tree assumes a broad round head, with a very graceful outline, being well furnished with slender delicate branches. The bark is of a grey ashen colour, very smooth, not unlike the Beech in this respect; the wood is fine grained, hard and firm, of a pale yellowish colour; hence its common name. The sap of this tree flows as abundantly in the spring from wounds made in the wood, as it does from the Sugar Maple, and it is also decidedly saccharine; but whether sweet enough to make sugar or not, is a point which I think has never been practically determined. The leaves are large, odd-pinnate, rich green, and smooth; flowers, white, or cream-white, about an inch long, and produced in drooping panicles a foot long. My specimen tree bloomed this season the last of May, and while the general appearance of the flowers reminds one of those of the common Locust, still, they are so much larger, and the general character of the foliage and habit of the tree so widely different, no one would be likely to confound the two. The seeds of the Yellow-wood are very similar to those of the common Locust, and grow quite as readily. The tree itself possesses sufficient merit to make it popular; but the masses have not as yet been made acquainted with it, hence its scarcity, even in good collections of other trees.—*Monte's Rural*.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

The Swamp Oak (Quercus palustris).—This Oak, as its name implies, grows more abundantly in swamps and low grounds than elsewhere, but it will thrive in any good rich soil, and its general form, when given plenty of room, is all that could be desired. It also possesses the additional merit of being valuable for its wood, either for fuel or timber. It thrives admirably in England, and we have seen some fine tall specimens of it in Surrey recently.

Beautifying Railway Lines.—During a recent ride over a portion of the Michigan Southern Railroad, we observed new plantings of lines of trees, of the European Larch and the Chestnut. They were mostly growing well. We were informed that the company had planted 219 continuous miles; the trees being 50 feet apart, it would require 125,000 trees of each sort. In a few years they will be worth more than ten times their cost.—*Cultivator*.

The Feathery Tamarix (T. plumosa).—M. Carrière says, in the *Revue Horticole*, "Nothing can be more graceful than this species, which is still rare in spite of the readiness with which it can be propagated. Its numerous slender branchlets, of a glaucous green hue, bear a certain resemblance to the curled plumes of the ostrich (or the white stork), whence its popular name of Marabout. It flowers in August, about the same time as T. indica. The flowers, which are disposed in dense erect panicles, have an airy lightness which adds much to the elegance of the foliage, isolated on a lawn or in a large park. T. plumosa forms a compact mass of the most pleasing appearance; and is quite as hardy as T. indica, and is propagated and treated in precisely the same manner."

THE HOLLYHOCK FUNGUS.

(PUCCINEA MALVACEARUM.)

A TERRIBLE pest—one of the most destructive since the disease which worked such ravages in 1855-57—is at present attacking Hollyhocks and destroying all hopes of fine bloom. It appears on the under sides of the leaves in the form of brown spots that gradually eat their way through to the top, and cause the leaves to shrivel as if withered through the effects of smoke. Its coming is as mysterious as its action is thorough. It settles down on a spot suddenly, and spreads over the whole plant, tainting stock and leaves alike. Not alone does it affect plants growing in the open air; it also appears on the young-struck cuttings in the autumn that are being nurtured in cold frames. It lays hold of the young weakly plants much as it does the vigorous ones in the open ground during the summer. The moisture that prevails during the autumn months makes resistance to the disease less powerful, and the plants die as if stricken down by a pestilence. Last autumn and winter Mr. Chater, of Saffron Walden, lost an immense number of newly-propagated plants, and though he employed sulphur and other remedies, they seemed merely to aggravate the evil. This season I met with one plantation of Hollyhocks that manifested a vigorous and healthy growth till the disease appeared; all the affected leaves were removed, and a good soaking of water was given to the plants; they rallied for a time, but as soon as dry hot weather set in the attack was renewed with redoubled force, and the plants were in a great measure completely destroyed. It does seem as if there was sound sense in the following recommendation, viz., "as soon as the disease appears, do not parley with it, but dig up the plants and destroy them root and branch at once." Mr. Speed, of Cambridge, informed me that the fungus had appeared among his plants there in a most virulent form, and, that after trying several remedies which suggested themselves, with but poor result, he was induced to make a trial of Condy's Patent Fluid, in what is known as the green quality, and used it in the proportion of a large tablespoonful to one quart of water, sponging and washing the leaves with it; a few hours after using it, he was gratified to find, that "it had completely destroyed the disease." A mixture made up of a tablespoonful to one gallon of water was next tried, and the effect was even more rapidly apparent—the pest being instantly killed, while the plants were uninjured. Preference is given by Mr. Speed to sponging over syringing; the latter occasions much waste, and though sponging consumes more time, it is by far the most effectual method of application. Mr. Speed is of opinion that if this remedy be applied in time, the progress of the fungus will be entirely arrested. The same grower is of opinion that when Hollyhocks are planted they should not be crowded together, as the effect of crowding is to intensify the effects of the disease. R. D.

Ants Enemies to Caterpillars.—The Belgian *Official Journal*, referring to the ignorant conduct of those who destroy all kinds of birds and insects indiscriminately, insists on the necessity of children in primary schools being taught to distinguish between useful and noxious insects, and thus to exercise their destructive faculties against the latter only. The writer proceeds to say that the ant, which is very disagreeable and inconvenient in many respects, does excellent service in chasing and destroying caterpillars with relentless energy. A farmer who had noticed this fact, and had had his Cabbages literally devoured by caterpillars, at last hit upon the expedient of having an ant-hill, or rather nest, such as abound in Pine forests, brought to his Cabbage plot. A sackful of the Pine points, abounding in ants, was obtained, and its contents strewn around the infested Cabbage plants. The ants lost no time, but immediately set to work; they seized the caterpillars by their heads. The next day heaps of dead caterpillars were found, but not one alive, nor did they return to the Cabbages. The value of the ant is well known in Germany, and although their eggs are in great request as food for young partridges, pheasants, and nightingales, there is a fine against taking them from the forests. The ant is indefatigable in hunting its prey; it climbs to the very tops of trees, and destroys an immense quantity of noxious insects.

What is Paris Green?—I shall be obliged by your informing me what this compound is, as I find frequent allusion to it as an insect destroyer.—A. [Paris green is a compound of arsenic and copper. We have often spoken of its use and given directions for operating with it. It was first used to destroy the new pest that infests the Potato in America, but since its introduction its use has extended, and it is now employed to kill other insects that infest other plants. It is a very poisonous mixture. The best way of using it is to stir a tablespoonful of the green in a pailful of water, and apply it with an ordinary watering-pot. The poison is not soluble in water, but is only diffused through it, hence it should be thoroughly stirred, and the liquid applied to the plants before it has had time to settle.]

THE INDOOR GARDEN.

ARECA LUTESCENS.

Our illustration represents one of the most elegant of all Palms, and one of the very best for general decorative purposes, being easily grown and useful in every stage of its growth. When from 1 to 2 feet high it is invaluable for table decoration; and, after it has become too tall for indoor or room decoration, it forms a handsome and effective object in the conservatory or winter garden. Our figure gives a good idea of a well-grown specimen, and shows at a glance its adaptability and elegance when associated with half-hardy Rhododendrons or other plants of less graceful contour and more rounded mass-like forms. The plant is easily obtainable, being grown in quantity in nearly all nurseries, and is well worth a place in every collection. Where seeds can be got they germinate freely in a genial bottom-heat; and, as this kind of Palm is a quick grower, seedlings soon become serviceable plants. A catechu is a handsome plant, cultivated in all the warmer parts of Asia for the sake of its fruits, which are of the size of a hen's-egg, of a reddish-yellow colour, and with a thick fibrous rind, within which is the seed. This is known under the name of Areca nut, Pinang, and Betel nut, and is about the size of a Nutmeg, but conical in shape, flattened at the base, brownish externally, and mottled internally like a Nutmeg. These nuts are cut into narrow pieces, which are rolled up with a little lime in leaves of the Betel Pepper. The pellet is chewed, and is hot and acrid, but possesses aromatic and astringent properties. It tinges the saliva red, and stains the teeth, and is said to produce intoxication when the practice of chewing it is begun. The effects seem to be as much due to the other ingredients as to the Areca nut. So addicted are the natives to the practice, that Blume tells us, they would rather forego meat and drink than their favourite Areca nuts, whole ship-loads of which are annually exported from Sumatra, Malacca, Siam, and Cochin China. The practice is considered beneficial rather than otherwise. In this country the charcoal of the nuts is used as tooth-powder, for which it is well adapted by its hardness. A sort of Catechu is furnished by boiling down the seeds of this Palm to the consistence of an extract, but the greatest quantity of the drug called catechu used in this country is the production of *Acacia catechu*. The flowers of the tree are very fragrant, and used on festive occasions in Borneo, where they are considered a necessary ingredient in medicines and charms employed for healing the sick. In Malabar another species, *A. Dicksoni*, is found wild, and furnishes a substitute for the true Betel nut to the poorer classes. *A. oleracea* is the Cabbage Palm, which is found in abundance in the West Indies. It derives its name from the bud which terminates its lofty stem. This bud consists of a great number of leaves densely packed, so that the inner ones are of a white colour and delicate flavour, and serve as a vegetable. The noble trees are destroyed for the sake of this luxury; and it is related that in the cavity, formed by the removal of the

"cabbage," a kind of beetle deposits its eggs, from which maggots are produced which are an article of diet much relished by the negroes of Guiana! C.

TROPAEOLUM TRICOLORUM.

Those who have little greenhouses to keep gay at a season when flowers are scarce, will find this a most useful plant for the purpose; but, in order to have it in anything like good condition, it must now receive attention, and have everything prepared for giving it a fair opportunity for doing credit to the cultivator during the ensuing season. There are several varieties of *Tropeolum* in cultivation, each claiming more or less the attention of those who take a pleasure in growing such

plants, but this is the one with which I have had most experience. Having a few small roots of it, and having taken example from neighbours who grew it to great perfection, I soon increased their number, until I had them in abundance. I first flowered a few roots in 32-sized pots, and having a few small branches of Birch, with the slender tips cut off, I placed one or two, as were required, in each pot, and allowed the plants to grow carelessly about all over these supports; while, of course, at short intervals, whenever any leader required guiding and laying into some desired position, this was done. Seldom, if ever, were any ties required, as their leaves soon twisted their slender foot-stalks round their supports. *Tropeolums* of this class can be trained in various forms, to suit the fancy of the cultivator. The most natural shapes, however, look best. In increasing the number of roots I never, as a rule, adopted the plan of taking cuttings off the young shoots. This system requires much care and a good deal of practice to be at all successful; and I seldom have seen it tried in ordinary gardens. Even some expert propagators have found no small amount of difficulty in getting such cuttings to root. My plan was somewhat as follows, and was, in general, pretty successful:—The soil in which I grew them was well-rotted turfy-loam, with sometimes a small portion of turfy-peat, and, whatever the nature of the soil might be, I added to it about a quarter of

Areca lutescens.

its bulk of good white sand with plenty of potsherds, putting a small portion of Moss or some turfy substance over the potsherds, thus securing ample means of drainage at the bottom as well as porous soil, as roots of this *Tropeolum* are very impatient of stagnant moisture, which soon gives the plants, more or less, a yellowish and unhealthy appearance. Indeed, by way of trial, and to secure drainage, especially after I took to growing them in large pots, I have, in addition to the ordinary good drainage at the bottom, placed up in the middle of the pot two or three handfuls of half-rotted bents off peaty soil. The way I in general adopted to increase the number of roots was somewhat as follows, and whether the pot might be small or large, much the same method was adopted. As I have already stated, the character of the materials generally used was porous, and after I had secured a good many roots and taken to grow them in large pots, I have often

had six or eight good-sized roots in one pot. I filled up the pots much in the usual way, but large pots are best, having two or three side holes at the bottom, thus securing a more uniform and safe means of drainage. After securing clean well-drained pots, of the size required, I proceeded to fill up with soil, as described above, until about two-thirds up the pot was full. Then, however many roots you may intend putting into any pot, place them round at equal distances, and, if a large pot, about 2 inches from the side, of course leaving 6 or 7 inches in the middle, in which the top of some small tree should stand, which they will by and by lay hold on and ramble all over. Having placed the roots in the position desired, I covered them as I filled up the pot with soil, about 1 inch; after which I placed the pots in a cool part of a greenhouse, or into a cold pit, upon coal ashes or burnt clay. These were some inches thick, so as to allow all surplus water to pass away very freely. When they begin to grow they require some attention, so as to prevent the shoots from becoming entangled or matted together. When they had grown some 6 or 8 inches in length, I gently bent the shoots at a joint and buried them in the soil, leaving a few inches uncovered; this operation I kept repeating, gently bending them a few times more, if an increase in the number of roots is required. Of course, I only fill up the soil in the pots to a proper depth from the top, and as I bent these young growths for the last time, I let them incline towards the middle of the pot. In most cases they will make a small root at each bend, and soon lay hold of the stem of the miniature tree, up which, by a little guiding, they soon ascend. The top of a young Larch, when of a close and uniform shape, makes the best support. When potted, I placed them in a cool house, where they had plenty of air, or in a cool pit; but, in either case, they were allowed to stand upon ample drainage. This species of *Tropæolum* does best without forcing. If started in a cold pit, it should be removed to a cool house by the beginning of December. The temperature in which greenhouse plants will grow well will answer for it admirably, and, as the plants of it go on growing, continue to regulate the young shoots so as to give them as uniform a shape and as handsome an appearance as possible. They can be made to come into flower pretty early in the spring, and they will continue in perfection a long time. I have often seen good specimens of them at spring shows some years ago, where they were much admired; but, nowadays, such plants seldom find their way to exhibitions.

Barnet.

G. DAWSON.

How to renovate neglected Camellias.—I have a number of Camellias which have been much neglected and have made no growth this year. Would you advise me to cut them down now and place them in heat, or wait until spring. I find that one or two are just beginning to break, but the others do not seem to move.—J. G., *Croydon*. [Reply by Mr. Baines:—The Camellias, the condition of which has just been described, are doubtless weak at the roots, either from having at some time during the winter, or spring, been allowed to get too dry, with, most likely, an insufficiency of moisture in the atmosphere; or through effects produced by the opposite cause, too much water at the roots, by which the latter have more or less perished. The former is the most likely cause, yet continuous neglect and bad treatment in any way will produce the condition complained of. They must on no account be cut down now, or in the spring, nor until the roots are brought into a more healthy and active state; or most likely they will die. The object in cutting back Camellias is to induce a more bushy habit when they have got into a thin straggling condition, but the operation must never be attempted where the roots are deficient or in a bad state. With plants in the condition described, the best treatment is to at once see whether they are dry in the centres of the balls, and, if that be so, to fully immerse them in a tub of water for twelve hours, so as to moisten them through. Attend to their requirements during the winter, by not allowing the atmosphere where they are grown ever to get parchingly dry, even during severe weather, when fire heat is required. Evergreen plants having a large leaf surface, like the Camellia, under such conditions of the atmosphere, lose more by evaporation than they can withstand. In the spring, as soon as they show signs of growth, keep the house a little closer so as to encourage them to push freely. Syringe overhead, and keep them sufficiently, but not over, watered. Thus treated, they may be expected to acquire invigorated root action, and a generally better condition. Then, in the following winter, if the plants are thin and straggling, they may be headed back soon after Christmas, and at once placed in

a temperature of 50° at night, allowing a little higher temperature by day. In this they will break freely, and, if well treated, should make two growths before the end of the season.]

A New View of Draining Flower Pots.—Mr. Peter Henderson, who grows hundreds of thousands of pot plants without drainage, writes to this effect in a contemporary:—The question of drainage is not whether plants require it or not; we all agree on that. But the question is in what way the water passes from the pot; whether from the bottom or whether from the sides. We who advocate that the practice of crocking pots is useless, claim that nine-tenths of the escape of moisture is from the sides; they who practice "bottom drainage," would signify by so doing, that, in their opinion the escape of water is mainly from the bottom. If anyone wishes to decide this question for himself, let him take half-a-dozen glazed pots, such as water will not percolate through, let him knock the whole bottom out if he will, and "drain" in the usual way with potsherds, charcoal, or anything else he thinks fit. Let him also take half-a-dozen of the ordinary style of flower-pot. Fill these up with the same soil as used for the glazed pots, but without drainage. Let the same sort of plant be grown in each lot, and under the same conditions of temperature and moisture. Let him note the result three weeks after the experiment has been made, and if he does not find that the glazed pots, with the bottom drainage, show indications of stagnant water in a greater degree than those in the porous pots, then all my observations on this subject have gone for nothing. If I am correct in this, does it not most emphatically prove that the escape of moisture is nearly entirely from the sides of the pot, and not from the bottom, and hence the futility of placing potsherds in the bottom for drainage?

The Old Shrubby Mimulus (*Diplacus*) glutinosus.—This, when well-grown, is a fine plant for conservatory or greenhouse decoration. We recently saw at the Birmingham Botanic Garden, some dense bushes 3 feet through or more, which were literally masses of flower. The plants had received nothing beyond ordinary greenhouse treatment, and were turned out-of-doors with other greenhouse plants as early as possible in the summer, being again brought into the positions required when they reached the flowering stage. The Rev. H. N. Ellacombe, of Bitton, states that with him this plant is as hardy as a Fuchsia—i.e., it dies down in the winter and comes up strongly in the spring; plants that have certainly stood out more than ten years, have this season flowered well. "I am sure," he adds, "that there are many plants of the same sort that would do very well treated in this way—i.e., as herbaceous plants. *Datura sanguinea* is now in flower; it has stood out a dozen or fifteen years; it dies down every winter, and comes up early, and does not seem to be affected by the spring frosts; treated in this way the flowers and foliage are far finer than those usually seen in greenhouses."—*Florist*.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Poinsettia pulcherrima rosea-carminata.—This fine variety of one of the most useful of winter decorative plants resembles *P. pulcherrima* as regards foliage, the difference consisting in the colour of the fine-spreading head of bracts, which are of a brilliant rosy-carmine hue. In one specimen which has come under our observation, the crown of coloured bracts measured 15 inches across; the inflorescence first branched trichotomously, and then each of these branches was forked. The number of bracts displayed on these six ramifications was forty-five, all perfect in form, and pure in colouring, the larger ones measuring 7 inches in length, and upwards of 2 inches in breadth. The bracts are much smoother and flatter than in the old form, and spread out so as to form a fuller and more regular crown.

The Best Cool Orchids.—I shall be glad of the names of the best cool Orchids that may be grown in a combination Orchid and greenhouse, sufficiently heated to keep out severe frost.—E. W., *Liss*. [*Odontoglossum grande*, *O. luteo-purpureum*, *O. Alexandrie*, *Cypripedium insigne*, *C. barbatum*, *C. villosum*, *C. caudatum*, *C. Lowii*, and *C. Schlummi*, *Calogyne cristata*, *Cymbidium Mastersii*, *Dendrobium nobile*, *Laelia autumnalis*, *L. albida*, *Oncidium leucocichilum*, *Maxillaria Harrisonae*, *Lycaste Skinneri*, *Masdevallia Lindenii*, *M. Harryana*, *M. Veitchii*, *Laelia purpuracea*, *L. majalis*, *L. acuminata*, *Zygopetalum maxillare*, *Z. Mackayi*, *Anguloa Clowesii*, *A. unicolor*, *Calanthe veratrifolia*, *Pleione lagenaria*, *P. maculata*, *P. humilis*, *P. humilichii* (præcox), *Maxillaria venusta*, *Oncidium cucullatum*, *O. macranthum*, *O. serratum*, *O. zehnum*, and *O. tigrinum*.]

Propagating Indian Shot and Castor Oil Plants.—What is the best method of propagating these, and how should they be treated when taken out of the flower-beds in autumn?—GAWKAR. [When taken up in autumn, Indian Shot or *Canna*s should be placed in any dry situation where they will be protected from frost during winter. About the middle of March the tubs should be divided into as many pieces as contain strong eyes; these should then be potted and placed in a gently-heated house for a week or two, when they should be gradually hardened off by exposing them more freely to air. The Castor Oil plants (*Reinmens*) when cleared off the beds, should be conveyed to the rubbish-heap, and young plants raised afresh from seeds, which should be sown on a gentle hot-bed in February. As soon as the seedlings are strong enough to handle they should be potted off singly into tubs or small 6-sized pots; and, as soon as they fill these with roots, they should be shifted into larger-sized pots, and they will become strong plants by the middle of May. If *Canna*s are sown early in February, and pushed on in heat, they make large plants in 6-inch pots before the beginning of June, and the same applies to Castor Oils, which can also be sown in autumn, and, wintered in a small state in a warm greenhouse, make fine plants the following season.]

THE KITCHEN GARDEN.

POTATO CULTURE IN MARKET GARDENS.

LONDON market gardeners only grow early sorts of Potatoes for sale, late kinds, if any are grown, being only for private use. The varieties which they cultivate for market consist chiefly of Ashleafs, particularly Myatt's, Lapstone Kidney, Dalmahoy, Regents, and similar kinds. Young Potatoes from Nice appear in our markets soon after New Year's day, and shortly afterwards they are supplied from Algiers and the south of France. These early Potatoes, which are not of the best quality, are sold in 1 lb. punnets at from 1s. 6d. to 8s. per punnet, according to their quality and the earliness of the season. About Christmas and New Year's day, may be also observed in fruiterer's windows, little punnets of what are termed new Potatoes, which may be bought for 1s. and 1s. 6d. per punnet; these are the produce of tubers kept from sprouting till July, when they are planted. Haulm soon afterwards appears and tubers are formed; but the frost overtakes them long before the latter become firm or ripe; the haulm is then cleared off, and the ground is mulched with litter; about Christmas time these immature Potatoes are dug up, and after being steeped in water in order to soften them, they are exposed for sale labelled "New Potatoes." The ground selected for Potatoes, if an open quarter, is usually the driest and lightest at command, as in such soils, the crop comes to maturity sooner than it otherwise would do, and tubers raised in such soils are of the best quality. Mr. Myatt, of Deptford, a great grower of Potatoes, plants them in rows 2 feet apart, the ground being previously manured and trenched, and levelled down with the plough. Planting takes place as soon after the middle of February, as time and convenience will permit. Mr. Jessop, of Chiswick, on whose ground I have seen splendid Dalmahoy Potatoes, plants in drills $2\frac{1}{2}$ feet apart, and about 18 inches set from set in the rows; and, being planted in March, they are in excellent condition for use in August and September. Mr. Dancer, of Little Sutton, and others, plant two rows of Potatoes between their lines of Gooseberry and Currant bushes, which are 6 feet apart, and partially under the shade of large fruit trees, and when fruit bushes do not occupy this position the Potatoes are planted in continuous rows about $2\frac{1}{2}$ feet apart, just as they would be in open fields. Some market gardeners loosen the soil between the rows of their spring Cabbages in March with a steel fork, *i.e.*, if the ground had not been trenched before planting it with the Cabbages, and therein plant Potato sets with a dibber. When the Potatoes appear above ground the Cabbages are removed for market; therefore, little or no injury happens to either crop, and, as soon as the Potatoes get up a little and some earth is drawn to them with a hoe, the intervening space, if hard, is loosened with a fork, and again planted with Brussels Sprouts or early sprouting Broccoli. Before these can do much injury to the Potatoes, the latter will be ripe, when they may be lifted at once for market, or kept for seed or home consumption. In cases in which Potatoes are grown in the open fields, a crop of Lettuces may be got from between them, but after these are removed it is not considered advisable to plant anything else, particularly if the crop is to be sent to market. No sooner are the tubers all lifted, than the haulm is collected and carted to the manure heap; and the ground is then manured, or not, according to circumstances, and ploughed or dug over, when it is ready for Cabbage sowing, Colewort planting, Leek transplanting, or, for sowing with winter Onions; or it is used for Spinach, Radishes, Turnips, or late Celery. The summer culture consists in merely hoeing and keeping the crop rigidly clean. Potato crops are always earthed up, an operation which is done by means of broad iron hoes, or double moulded horse-ploughs, and they are, as a rule, lifted with forks, but sometimes by the plough, which performs the task more expeditiously. The tubers being collected and sized, are put into bushel and half-bushel baskets and are covered with haulm, which is held in its place by means of a few twigs of Hazel. These baskets are then piled one above the other on waggons and sent to market.

F.

VARIETIES OF LEEKS GROWN FOR MARKET.

THERE is an extensive demand for Leeks during the autumn and winter months. The varieties usually grown in market gardens, are the London Flag, a tall thick-stemmed sort, with broad leaves, and the Musselburgh, which is not unlike it, but which has a longer neck, and, being hardier than the London Flag, is more suitable than it for the main winter crop. The first sowing, for which the London Flag is used, is made in a frame on a gentle hotbed in the last fortnight in January or first fortnight in February, or it may be delayed until a frame can be emptied of Lettuces, a crop generally grown in that way. The hotbed is made by casting out a 5 feet wide trench 18 inches deep, and any convenient length, filling it with fermenting manure, over which the frames are placed. A few inches deep of soil are put inside and levelled; the seeds are then sown thickly, and covered by sifting some soil thinly over them. The sashes are replaced and tilted up a little, both night and day, if the weather is fine; but, if windy or frosty, they are kept shut, and a mulching of litter is put over the glass, if necessary, for protection. After the seedlings have appeared, covering at night is continued, but the frames are ventilated more or less during the day, if the weather is at all favourable. Weeds are kept in check, and where the Leeks are too thick they are thinned before planting out time has arrived, which is usually about the end of March or early in April. The first outdoor sowing is made about the middle of February, or as soon after that time as practicable, and is succeeded by another a month or six weeks later; a late sowing being made in the last week in April or in May. For Leeks, the ground is well manured, and they sometimes occupy it alone, but more frequently Lettuces are planted between the rows of Leeks. The ground having been well manured and deeply and loosely dug, lines are drawn as for Peas, about 10, 12, or 15 inches apart, and in these the Leeks are planted from 6 to 7 inches asunder. The first hoeing after planting fills up the little drills considerably, and the second one almost entirely closes them; thus, not only are the plants a little protected at first by being in the drills, but the hoeing earths them up, and causes them to have long white necks; besides, should the weather be dry at planting time, the little drills retain water better than partly-closed holes on a level surface. Between the wider rows Lettuces are planted, and are sent to market before the Leeks are fit for use. Instead of intercropping between all the rows of a plantation formed of Leeks from the latest sowing, only every alternate second or third alley is cropped. I have seen Leeks planted between Asparagus beds, lines of Beet and Parsley, and, in Mr. Dancer's grounds, between rows of Strawberries. Mr. Dancer, however, stated that want of space alone induced him to plant Leeks in such a situation, and asserts that Strawberries should never be intercropped. By the end of July or the beginning of August the produce from the first sowing is usually marketable, and it does not pay the grower to keep it on the ground longer, as, during the extra time it occupies the ground after being fit for use, a crop of Lettuces, Spinach, or Radishes might be taken from it. Leeks for market are stripped of their outside leaves, and the roots are washed, and tied up into fan-shaped bundles consisting of six or eight heads. Some of the finest examples of the middle or main sowing are usually marked (by inserting pegs alongside of them) and kept for seed-bearers. When the field is cleared, these are lifted and planted in some sheltered corner, where they are allowed to bloom and ripen their seeds. W.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Duke of Edinburgh Cucumber.—We have been eating this 32 inches long, and of tolerably good shape and flavour. Still, for usefulness there is nothing I find like true Telegraph, from which twice as many fruit is obtained. The Duke, however, is better than the Marquis of Lorne, which with me is decidedly an inferior kind.—R. GILBERT, *Burghley*.

A Plea for the Crow Bar.—I would strongly advise Cabbage growers to lose no time in pricking out their plants, in order that they may gain strength to enable them to stand the winter. Immediately the Onions are off the ground, it should be hoed, raked, and, without any digging, holes should be made in it with a crow bar, and the plants washed in with a thorough soaking of water. By adopting this plan, all the Cabbage is ready to cut at one time, and, by clearing out any single row, and planting Scarlet Runner Beans, you will find the Cabbage retained a great shelter to the Beans.—R. GILBERT, *Burghley*.

THE HOUSEHOLD.

THE USES OF THE APPLE.

THE Apple comes nearer to universal uses than any other fruit of the world. Is there another that has such a range of season? It begins in July, and a good cellar brings the Apple round into July again, yet unshrunk, and in good flavour. It belts the year. What other fruit, except in the tropics, where there is no winter, and where there are successive growths, can do that? It is a luxury, too. Kinds may be had so tender, so delicate, and so refreshing, that not the Pear, even, would dare to vie with it, or hope to surpass it. It may not rival the melting qualities of the Peach, eating which one knows not whether he is eating or drinking. But the Peach is the fruit of a day—ephemeral; and it is doubtful whether one would carry through the year any such relish as is experienced for a few weeks. It is the peculiarity of the Apple that it never wearies the taste. It is to fruit what wheaten bread is to grain. It is a life-long relish. You may be satisfied with Apples, but never cloyed. Do you remember your boyhood feats? I was brought up in a great old-fashioned house, with a cellar under every inch of it, through which an ox-cart might have been wheeled after all the bins were full. In this cellar, besides Potatoes, Beets, and Turnips, were stored every year some hundred bushels of Apples—the Rhode Island Greening, the Roxbury Russet, and the Spitzenberg; not daintily picked, but shaken down; not in aristocratic barrels set up in rows, but ox-carts full; not handled softly, but poured from baskets into great bins, as we poured Potatoes into their resting-place. If they bruised and rotted, let them. We had enough and to spare. In all my boyhood I never dreamed of Apples as things possible to be stolen. So abundant were they, so absolutely open to all comers—who went down into the cellar by the inside stairs instead of the outside steps—that we should as soon have thought of being cautioned against taking Turnips, or asking leave to take a Potato. Apples were as common as air. And that was early in December and January; for I noticed that the sun was no more fond than I was of staying out a great while on those Litchfield hills, but ran in early to warm his fingers, as I did mine. Cloyed with Apples? To eat an Apple is to want to eat another. We tire of Cherries, of Peaches, of Strawberries, of Figs, of Grapes, but never of Apples. Nay, when creature comforts fail, and the heart—hopeless voyager on the troubled sea of life—is sick, Apples are comforters; or, wherefore is it written:—"As the Apple tree among the trees of the wood, so is my beloved among the sons. I sat down under his shadow with great delight, and his fruit was sweet to my taste. He brought me to the banqueting house, and his banner over me was love. Stay me with flagons"—undoubtedly of cider!—"comfort me with Apples, for I am sick of love."

If this is the cure of love, we may the better understand why the popular instinct should have resorted to the Apple tree as a cure for ambition, singing—

We'll hang Jeff Davis on a sour Apple tree.

There is, in this toothsome-ness of the Apple, together with its utter harmlessness, a provision for nurses and mothers. There is a growing period, when children are voracious. They must be filled; and it is a matter of great account to know what to fill them with. If you give them but bread, that seems meagre. Pies, cakes, and sweetmeats, are mischievous; and yet more so are candies and confections. Apples just hit the mark. They are more than a necessary of life, and less than a luxury. They just stand half-way between bread and cake, as wholesome as one and as good as the other. But now I enter upon the realm of uses, culinary and domestic, where, were I an ancient poet, I should stop and invoke all the gods to my aid. But the gods are all gone; and next to them is that blessing of the world, the housewife. Her I invoke, and chiefly one who taught me, by her kitchen magic, to believe that the germ of civilisation is in the art and science of the kitchen. Is there, among fruits, one other that has so wide a range, or a range so important, so exquisite, so wonderful, as the range of the Apple in the kitchen? First, consider it as a fruit-vegetable. It might with great advantage take its place

upon the table as regularly as the Potato or the Onion. Far more odorous is the Onion, but, I think, far more blessed is the Apple. It is an admirable accompaniment of meat, which always craves a piquant acid for relish. We do not use the Apple enough in our cooking. As a fruit upon the table it may be used for breakfast, for supper, for dessert. Roasted Apples! Baked Apples! What visions come before my mind! Not the baked Apples of the modern stove, which has humbled their glory. They are still worth eating, but they have lost the stature, the comeliness, and the romance of the old roasted Apples, that were placed in due order between the huge hand-irons, and turned duly by the careful servant, drinking in heat on one side and oxygen on the other, and coming to a degree of luxurious nicety that will never be attained till we go back again to the old fireplace. It was a real pleasure to be ill—I mean on the lither border of sickness—so that we might not go to school, and so that, while we took a little magnesia, we might feast on delicious roasted Apples. And as for baked Apples and milk, how can I adequately speak of the most excellent dish? Then, again, the Apple may be regarded as a confection, serving in the form of tarts, pies,—blessed be the unknown person who invented the Apple-pie. Did I know where the grave of that person was, methinks I would make a devout pilgrimage there, and rear a monument over it that should mark the spot to the latest generations. Of all pies, of every name, the Apple-pie is easily the first and chief. And what shall I say of jellies, dumplings, puddings, and various preserves, that are made from the Apple? It might seem hard, in this enumeration of the many forms in which the Apple is made to contribute to the benefit of mankind, not to notice that form in which it defies age: I refer to the dried Apple. No festoons are more comely than were those half circles that used to decorate the rafters of the old-fashioned kitchen. I confess that no dried fruit is worthy to be called fruit, whether it be Huckleberry, or Peach, or Pear, or Apple. Once dried these things have lost the soul of their flavour; and no coddling, no soaking, no experimenting will ever bring them back to what they were in their original fresh life. Next, we naturally consider the use of Apples as food for stock—for swine, for horses, and for cattle. This use of them is known; but, it seems to me, that they are not thus employed near so much as their benefits would justify. Last of all, let me speak of cider; for, although cider has been banished from its former and almost universal position upon the table, it is creeping back again. Not daring to come in its own name, it comes in the name of a neighbour, and is called champagne. But whether it comes in one form or another, it still is savoury of the orchard; still it brings warmth to chilly veins; still it is a contribution to many a homely domestic festival. And though I cannot, as a temperance man, exhort you to make it, I must say that if you *will* make it, you had better make it good! It only remains that I should say a single word on the subject of the Apple as an article of commerce. Whether fresh or dried, it is still, in that relation, a matter of no small importance. The home market is enlarging every year; and as soon as the Apple shall become so cheap that all men may have it, no matter how poor they may be, the market must of necessity have become very much augmented. Many men suppose that as orchards increase and fruit multiplies the profits diminish. Such is not the fact. As the commoner kinds multiply, and the people learn to use them as daily food, the finer kinds will bear proportionally higher prices; and cheapness is one of the steps to profit in all things that are consumed by the community. And I should be glad to see the day when, for a few pence, every drayman, every common labourer in every city, should be able to bring as much fruit to his house every day as his family could consume in that day. We have not merely in view the profits of raising fruit when we exhort you to bestow your attention on the Apple more and more as an article of commerce; we have also in view the social influence which it may be made to exert. I hold that when in any respect you lift the common people up, whether by giving them a better dwelling, by placing within their reach better furniture, or by enabling them to furnish their table better, you are raising them toward self-respect; you are raising them toward the higher positions in society. And every single step of advance in general cultivation, even though it is brought about by so humble an instrumentality as the

multiplication of fruit, or anything else that augments the range of healthful enjoyment among the common people, not only stimulates their moral growth, but, through that growth, gives the classes above them a better chance to grow.

H. W. BEECHER.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

The Flower Garden and Pleasure Grounds.

The value of plants for flower-garden decoration depends, in a great measure, upon the length of time which they will remain in a state of perfection; and, on this account, it is advisable to make a careful inspection of the parterre about the present time, and to make notes of the condition of the various species of plants used therein, and their apparent adaptability for the purposes for which they are intended. A slight falling off may now, doubtless, be perceived among flowering plants generally; while plants grown chiefly for the beauty of their foliage, are now in considerably better condition than they have been at any other time during the present season—beds of sub-tropical plants being now at their very best; and the same may be said as regards beds of ornamental-foliaged *Pelargoniums*, succulents of various sorts, such as *Echeveria metallica*, *Sedums*, and *Sempervivums*; while the different varieties of *Alternanthera* are now assuming the beautiful tints for which they are so remarkable, and which, owing to some peculiarity of the present very exceptional season, have been absent until very lately. The moderate rainfall which we have recently had, together with the cool refreshing night dews, have, to some extent, enabled such species of bedding plants as the dwarf *Ageratums*, *Petunias*, and *Verbenas*, to furnish, to some extent, material suited to the formation of cuttings, and this circumstance should have immediate attention. In ordinary seasons cuttings of such plants would, in most instances, have been already rooted, and placed in the open air to become somewhat hardened before the advent of wintry weather. This, however, has not been practicable during the present season in most localities. It is quite unnecessary, however, to propagate at the present time anything like a large stock of such plants as the *Ageratum*, if a few store pots can be preserved over winter, or even a few old plants from the beds, they will seldom fail to furnish an unlimited supply of cuttings during the following spring. It is necessary, however, to keep such plants as the *Alternanthera*, Dwarf *Ageratum*, *Coleus*, and *Iresine*, in a somewhat genial temperature, during winter, and they can hardly be kept in a healthy condition in a temperature under 50°. Any time during next month is sufficiently early to insert cuttings of the various sorts of bedding *Calceolarias*. Allusion has formerly been made to the unfortunate habit to which this family of decorative plants is so exceedingly liable, namely, that of suddenly dying off, without any discoverable cause, and, successful growers of these plants, would confer a very considerable benefit upon many of your readers, were they to state in your columns the names of such varieties as they may have successfully cultivated during the present very trying season, detailing at the same time their method of treatment. The herbaceous border should still be gay with many late-flowering plants, conspicuous among which will be the *Tritoma Uvaria*, *Anemone japonica*, various sorts of herbaceous *Phloxes*, *Asters*, hardy *Fuchsias*, *Helianthus*, *Solidagos*, and *Eupatoriums*. As the flower-spikes of *Gladioli* decay they should be neatly cut off, without, however, injuring the foliage; and, when the stems of the herbaceous *Lobelias* die down it is advisable to remove the roots into the reserve ground, there to be slightly mulched or covered up for protection during the winter; and when they have started into growth in spring they can then be divided and re-planted. Gather seeds of whatever annual flowers may be required, and as soon as this is done let them be at once cleared off the herbaceous border, and replaced by spring-flowering *Stocks*, *Wallflowers*, and other biennial plants, together with spring bulbs of various sorts, which should be all carefully labelled when planted, to prevent them being injured by the digging or cleaning of the border. A few seeds of some of the finest annual flowers should now be sown in the reserve garden; they may be found to be useful for transplanting into the mixed herbaceous border during the spring. Prepare beds for the planting of early spring bulbs, wherever this can be done. But in most cases, such bulbs will have to occupy the beds and borders which are still gay with bedding plants, and cannot, of course, as yet, be interfered with. Recently-budded *Rose stocks* should be occasionally examined, and the tying material should be loosened where necessary, or, in some instances, may be removed altogether. Keep gravel

walks and drives free from weeds, and the litter of falling leaves, &c., and let them also be well rolled after a fall of rain. About this time worm-casts are exceedingly troublesome, and will soon spoil the finest gravel, unless they are carefully removed before they become mixed with it, and to prevent this, as far as possible, they should be picked up by the hand, and a little salt should, from time to time, be thrown upon the surface of the gravel, in order, if possible, to drive the worms away. Mow, roll, and frequently sweep Grass lawns and belts, in order to secure, as far as possible, a close solid green sward for the winter.—P. GRIEVE, *Culford, Bury St. Edmunds*.

Hardy Flowers.

The number of these in flower is weekly becoming less; but, by a little forethought, a considerable amount of bloom might still be maintained. For instance, if a few *Delphiniums*, double-flowered *Pyrethrums*, *Antirrhinums*, *Pentstemons*, and *Phloxes* were cut back very early, they would send up fresh shoots that would now be in full bloom. Herbaceous *Asters* will now rank amongst the chief features of the herbaceous or mixed border, especially such varieties as *Amellus*, *linearifolius*, *versicolor*, *sagittifolius*, *punctatus*, *Shortii*, *rigidus*, *discolor*, *hyssopifolius*, and others. They should be staked to prevent breakage by wind. The two varieties of the double-flowered *Helianthus multiflorus* are perhaps the most showy of herbaceous plants at present, and fit companions for these are the *Rudbeckia Neumannii*, *columnaris*, *speciosa*, and *purpurea grandiflora*, which are all grand, showy, and free-blooming hardy autumn flowers. *Arundo conspicua*, too, is a fine object, either in the form of isolated specimens on lawns or in borders, and will soon be followed by the more stately *Pampas Grass*, which should receive occasional thorough soakings of water. *Eupatorium purpureum* will be in bloom in the latter part of the month, and looks well planted near ornamental waters, and *Solidagos* will now be beautifully in bloom in our shrubby borders, and in back lines in herbaceous borders. The hardy *Fuchsias* are, perhaps, the most attractive of September plants, and *Veronica salicifolia*, too, is another plant now in great beauty, as is also the *Tritoma Uvaria*. Amongst the smaller plants that bloom in September may be mentioned *Sisyrinchium convolutum*, a pretty little yellow flower; *Vittadinia triloba*, a Daisy-like blossom, with the good property of keeping long in bloom; *Corydalis capnoides alba*, an interesting white form; the little yellow *Achillea Ageratum*, *Statice* of various sorts, *Linaria alpina*, *Lythrum floccosum* and *L. alatum*, *Anemone japonica*, white and rose; Japan *Lilies*, *Erodium macradenum*, *Buphtalmum maritimum*, *Zapasia nodiflora*, *Sedum spectabile*, *Asclepias tuberosa*, and *Cyclamen hederifolium*. Cut over all decayed and decaying flower-spikes, and remove withered leaves, so as to secure cleanliness. Alpines and other plants in pots should now be looked over, cleaned, re-potted, and placed in cold frames. Transplant *Iris*s, and thin the blooms of choice *Chrysanthemums*.

Calceolarias.

Towards the end of the month, frames must be got in readiness for the winter stock of these, no matter whether it be cuttings or old plants that are to be saved. These frames may either be made of wood or turf, and they must be set upon a well-drained bottom covered, a few inches deep, with ashes. Over this put 6 or 7 inches in depth of sandy loam, mixed with a little leaf-soil; and on the surface place half-an-inch layer of pure sand, beating all pretty firmly. No heating material whatever will be necessary in winter, covering the sashes with some protecting material being sufficient. In the last fortnight of the present month, and during any part of October, the cuttings may be successfully put in, about 2 inches apart, and shaded for a little time afterwards. Short stubby laterals should be chosen for propagating purposes, and all should be rejected that have visible flower-buds. Dusting with dry wood ashes now and then is a good preventive of the damp that often proves so destructive to them. Such varieties as thrive best in the locality should be most extensively increased. *C. aurea floribunda* does not do well near London; whilst, in many other parts of England and in Scotland, it is the best of all *Calceolarias*. *Gaines's Yellow* is the sort most cultivated about London; and *amplexicaulis*, too, does even better than it; but its habit is so loose that we want, for general purposes, a variety having a stocky habit, and, if possible, the blooms of *amplexicaulis*. *Princess Helena*, a dark variety, does remarkably well in Lancashire. *Ambassador*, *canariensis*, *Prince of Orange*, *Aurantia multiflora*, *Havelock*, and *Golden Gem* are also good varieties for the flower garden.

Sub-tropical Plants.

These will now be at their best, and looking magnificently, set off, as they generally are, by a ground-work either of brightly-coloured leaves or bloom. *Cannas* are now finely in bloom, and the gigantic, but hardy, herbaceous *Polygonum Sieboldii*, is also now laden with flowers. Among smaller plants now in flower, *Vallota purpurea* is

one of the finest, and it is admirably suited for moderately-sized flower-beds. Erythrinæ now form conspicuous objects, being in full bloom, and the variegated Japanese Maize, now in flower, has a most effective appearance. Increase the stock of *Ficenses* from cuttings in heat, Palms from seed, Musas from seeds and suckers, but such annuals as Tobacco plants, and others, may be left unsown until early in spring.

Indoor Plant Department.

Lapagerias, which are perhaps the most beautiful inmates of conservatories at present, require abundant, but judicious, waterings, and slight shade from strong sunshine; *Zephyranthes rosea*, a pretty bulbous plant, is now, both in and out of doors, in great beauty, and *Pancratiums*, and even *Crinums* now in bloom, serve also to decorate the warmer corners of conservatories. *Cyclamens* demand particular attention just now; some of the young ones should be re-potted, and kept either in frames or placed on wood or ashes out of doors, and syringed twice a day. Cape *Pelargoniums* should be re-potted; old plants should be turned out of the pots, the soil shaken from their roots, and should be again re-potted into the same sized or perhaps a less sized pot, according to the strength of the plant, using a compost of good loam and leaf-mould, and a plentiful admixture of river sand. Plants of *Cyperus alteraifolius* intended for decoration throughout the winter months should be re-potted in a compost of yellow loam, a little fibrous peat or leaf-mould, some chopped Sphagnum, silver sand, and, finally, broken crocks. The plants should then be kept in a moist warm temperature for a time. Plants for the winter decoration of stoves should now receive attention, and among these the old *Justicia speciosa* is one of the most effective. As usually met with, this plant presents a leggy naked appearance, and it is frequently seen in this state where better things might be expected; but this is entirely the result of bad treatment, for the habit of the plant is good, although, like other free-growing subjects, it is apt to lose its bottom leaves and become leggy under bad management. Cuttings of it inserted in sandy soil and placed in a gentle bottom-heat root in a few weeks; and, in order to secure large specimens for blooming after a season's growth, the cuttings should be put in at once, so as to allow of having them rooted and well established in small pots before winter. They should be potted off singly in small pots as soon as they are fairly rooted, and placed near the glass in a moist rather shady part of the stove, or a warm pit, pinching out the points of the shoots as soon as the roots get hold of the soil, and stopping must be attended to during the growing season. In winter, place the young plants in any roomy situation near the glass where the temperature may range towards 50°, and keep them properly supplied with water at the root. About the beginning of March, or as soon after that time as convenient, remove them to where a growing temperature of about 60° is maintained by artificial means, allowing it to rise 10° or 15° with sun, heat, and air. Shortly after placing the plants in heat give them a moderate shift, using about equal portions of good rich turfy loam, peat, thoroughly decomposed cow dung or leaf soil, and sharp sand, well intermixed together. As soon after potting as the roots appear to have started into the fresh soil stop the shoots and tie them nicely out, keeping them well down, which will have the effect of causing the bottom buds to start into growth, and inducing a bushy habit of growth to begin with. As the season advances, and the plants get into free growth, give air freely on mild days, and keep them near the glass. Some of the *Franciscæas* will be still in bloom, and also *Gastronemas*, *Gomphias*, *Amaryllis reticulata alba*. The chief beauty belonging to our stoves, however, will be the many noble foliaged plants and fine Ferns which they contain. *Gloxinias* and *Gesneraceous* plants out of flower should be set in cold frames, where they should be kept dry. Some of the *Ardisias* should now be prettily laden with berries; others, particularly *A. villosa mollis*, on the other hand, will be in flower, and the plants should be removed to a drier atmosphere for a time, until the fruit has set, when they may be again placed in a moist heat. The finer kinds of Ferns should still receive a little shade, in order to preserve their colour. Stems of Tree Ferns lately imported should be wrapped round with damp Moss, which not only prevents such a frequent use of the syringe as would otherwise be necessary, most likely to the injury of the surrounding plants, but also obviates sudden vicissitudes of temperature.

Orchids.

The chief work now to be done in the Orchid-house is to keep the plants clean by repeated spongings. The use of the syringe may now, in the majority of instances, be suspended, except in the case of *Cypripediums* and *Disas*, which are greatly benefited by occasional sprinklings during bright sunny weather. Orchids making their growth should, if possible, be placed in a humid atmosphere and still have a plentiful supply of tepid water at the roots. This is especially applicable to *Odontoglossums*, as *O. Alexandræ*, *O. Pescatorei*, *O.*

nebulosum, *O. Uro-Skinneri*, and other species. The same may be said of *Masdevallias*, as *M. Harryana*, *M. Veitchii*, *M. coccinea*, and *M. Lindeni*, and the strong growing *Oncids*, as *O. macranthum*, *O. zebrium*, *O. serratum*, *O. obryzatum*, and others. All of the above grow best in the cool house, and if the pots in which they are growing be thoroughly well drained it is almost impossible to give them too much root moisture, especially if the weather is bright and open. Leave air on the cool houses night and day, using a little fire-heat on cold or stormy nights, but it must be borne in mind that these plants grow much more vigorously if they are wintered in a cool airy atmosphere. Plants at rest should be carefully attended to with regard to moisture at the root, as there are but very few which ought to become dust dry, as the rest of most *Orchids* is comparative rather than absolute, and this is especially the case with all but a few deciduous pseudo-bulbous kinds, of which *Calanthe* and *Pleione* may be cited as examples. If it is not already done, go through the whole collection and clean every inch of wood or iron-work with soft-soap and water, and re-arrange the plants so as to give each its due share of air and light. Shading may, in most cases, be now removed, unless the canvas rolls up under cover at the ridge of the house, in which case it may remain, as it is sufficiently protected from wet. It is now a good season to look out for a supply of peat, which is all the better for cultural purposes if stacked up under cover for some time before it is required.—F. W. BURBIDGE.

Nurseries.

Glass-houses should now be repaired, if necessary, so as to have them in trustworthy condition throughout the winter. Heating apparatuses should also undergo thorough examination. *Dipladenias* may still be increased by means of layers. One or more plants should be placed in a shady part of the stove; the shoots should then be loosened from the trellises, little pots should be filled with a peaty compost and finished with a layer of silver sand on the surface; these pots should then be placed in such a way that the joints of the shoots may be placed on them and held in position by means of a stone or peg. Under one shoot may be placed several pots, keeping one or two eyes clear between each pot. *Epiphyllums* may now be grafted on *Pereskia* stocks, on which they take freely, and do not require nearly so much attention, heat, or shade, as many other plants. *Camellias* and *Daphnes* may also be grafted in close propagating frames in intermediate houses. Conifers may be propagated by means of cuttings of the young wood; on some, however, a small piece of the old wood is retained. These should be placed in close frames or under hand-lights in cold frames and shaded. *Gloxinias* struck from leaves should be potted off singly as they become well-rooted. Out-of-doors, the training of young fruit trees should still be actively proceeded with. Cuttings of herbaceous plants, lately struck in pavis in frames should be potted off singly into thumb-pots, placed in cold frames, and kept well shaded for a time. Seed of all kinds should now be secured; what is ripe should be gathered, and what is not should be placed under the most favourable circumstances for maturation.

Indoor Fruit Department.

In Vineries in which Grapes are not yet thoroughly ripe the temperature must be kept much the same as directed for the last fortnight. All Grapes, which are expected to keep well for any considerable length of time, should be perfectly ripe by the end of this month, for sun-heat begins to diminish in October, and for imparting flavour and finish it far surpasses any kind of artificial heat. Where the wood of Vines to be started early is thoroughly ripe pruning should be proceeded with; cut the shoots clean over with a sharp knife, leaving two plump eyes on each spur. This is a wise precaution at all times, more especially in the case of Vines intended for early forcing, as they are sometimes shy in breaking, and if reduced to one eye, which does not always start, it causes a vacancy which disfigures the symmetrical appearance of the Vine. Where both grow the weakest can be rubbed off, when young, without injury to the Vine. As soon as pruning has been performed have a bottle of Thomson's Styptic, and with it dress the wounds. Prevention is at all times better than cure, and, although Vines may not bleed just when they are cut, they generally do so, more or less, when the sap begins to rise, unless dressed in the way just recommended. Wash the rods and wood-work well with a strong mixture of soft-soap and water. All repairs inside should be done before starting. When all are cleansed let the rods be secured to their permanent positions half-way up, leaving the point to droop down or somewhat suspended; this equalises the distribution of the sap, and induces the buds to break more evenly than they otherwise would do. Remove all the old soil down to the surface of the roots, and replace it with a rich mixture of good loam, ground bones, and a little well-decayed manure; this, brought up to the former level, has a wonderful influence in keeping the roots near the surface, which is a great point gained. As the inside borders

will not have been watered since before the fruit was ripe they will be very dry, and, if well drained underneath (as they should be), give them a good watering, in order that the roots may be in a growing condition before forcing is started. Admit a free circulation of air at all times, and have everything in prime order for a good beginning, which goes far towards securing a successful end. Suckers of Pine-apples should be potted as soon as possible, using good turfy loam only, mixed with a little charcoal; no water should be given until they begin to emit roots. To Fig trees swelling fruit a good supply of weak manure-water should be given, but it should be gradually lessened as winter approaches. Melons are, for the most part, cut, but where there are some yet to ripen additional heat should be given, by renewing the linings, &c. Cucumbers in pits should be well syringed at midday or early in the afternoon. Mushroom beds in pits, cellars, or similar places should be spawnd as soon as their temperature decreases to 85°. Kidney Beans may now be sown in 6 or 8-inch pots, half filled with a good rich open compost, leaving the other half to be made up when the plants come into bloom.—J. Muir, *Clovenfords*.

Hardy Fruit.

Late Peaches, and Peaches, Nectarines, and Plums, in late cold situations, may now need a little help in the way of glass or fire, where the walls are flued, to hasten and complete maturity. I have seldom seen October Peaches so late as this year. A Salway Peach, beside a tree of ripe Noblesse, hardly seems to have commenced the second swelling; Lady Palmerston is almost a month behind others in exactly the same positions; Walburton Admirable, Late Admirable, Desse Tardive, Princess of Wales, and others of Mr. Rivers's seedlings, are likely to be almost equally late; and, in the north, the common earlier varieties of fruit such as Elrige Nectarines, and Golden Drop and Imperatrice Plums, are likewise late. In all such cases it would be well to apply fire-heat at once. It is much easier to push fruit on now, when helped by the sun, than next month when the sun has but little power. In the heating of flued walls, great care is needful at first. As in running, it is the pace that kills, so in culture of all sorts, it is the suddenness of change that is the source of danger and cause of greatest mischief. The same danger, to a lesser extent, is incident to the covering of wall trees with glass, it should, if practicable, be done piecemeal. The principle I am anxious to lay down clearly (as it is the secret of success in the matter) is the superlative importance of tentative protection, if I may so express it. Gradually and imperceptibly the fruits find themselves led from the outside air to an enclosed atmosphere of superior temperature, and they go on growing without check, and finally finish at an augmented pace. But let the change be sudden, and many fruits will probably drop, and the remainder prove hard and almost worthless. To make up for the deprivation of natural dews and rains, late fruit trees, protected with glass, should be dewed heavily over every morning, for the double purpose of restoring the natural supply of moisture to the trees, and keeping down red spider. Late Peaches and Plums are so valuable for dessert as to be well worthy of more than all the attention one can bestow upon them. Late Pears may often be helped under glass screens to maturity, that otherwise would either not ripen at all, or prove of such inferior quality, as to be useless for dessert.—D. T. FISH.

Kitchen Garden.

Where forced Asparagus is required early—say, by the middle of November—the first bed intended for early production should have the tops cut off, and all weeds and rubbish cleared away, to let in the full force of the sun's maturing influence upon the crowns, so as to prepare them for the application of bottom heat about the middle of next month. Onions, when sufficiently ripened and harvested, should be tied in rather small bunches, about a dozen or so in a bunch, and hung up to the rafters in an open, or, at least, a thoroughly ventilated shed. They keep much better treated in this way than when laid on shelves; and, as frost does not injure them, all they require is shelter from the rains in some well-ventilated building. The earliest sown Cabbages may shortly be planted out, about 18 inches apart each way. This crop with us usually follows the spring-sown Onions. We always heavily manure and deeply cultivate for the latter; and, when they are cleared off, we hoe the ground over deeply, draw drills at proper intervals, and plant the Cabbage plants in the drills. Cabbages are gross feeders; and, where the land is poor, manuring and digging may be necessary; and also in light sandy soils, where the particles of soil rapidly consolidate, deep digging and manuring may advantageously precede every crop. Different soils, however, require different treatment to obtain the best result; and the nature of the sub-soil, coupled with individual experience, must be the guide as to the best course to adopt. I can only say, provided the land had been deeply trenched for the preceding crop, and was in good condition as to manure, the rotation, also, such as Cabbage following

Onions, being a proper one, I should not, in land similar to ours (heavy loam on Oolitic clay), deeply cultivate for Cabbage, as I have always obtained the best results, both as to earliness and productiveness (and especially the former), from planting in firm land. They obtain a firm hold of the soil immediately; and, as a consequence, a rapid but firm growth takes place almost uninfluenced by frost. As soon as the earliest sown Cauliflowers are large enough, they should be pricked out, about 3 inches apart, for the purpose of having short stocky plants for hand-glasses by-and-bye. Draw their roots through a puddle composed of soot and liquid manure, as a check to clubbing where it is known to exist; and it is a beneficial practice to adopt at all times in transplanting any of the Brassica family. A further sowing of Cauliflowers may now be made under glass, in boxes, or in a small frame. Those who depend upon one sowing never stand in so safe a position as where the plan of making several sowings at intervals of ten days or so is followed out, neither in the certainty of a crop, nor yet in what is of equal importance in a private garden—a continual succession. Make a last sowing in the open air of Lettuces. The Tom Thumb is a beautiful little Cabbage Lettuce for sowing now for frame-work by-and-bye. It is very hardy, occupies but little space, and turns in rapidly. The brown Cos should also be sown now for spring planting. A last sowing of Eudive may also be made now on a dry warm border. Where Leeks are planted in trenches, the earliest lot should now be earthed up; and, as we may shortly expect a considerable rainfall, all Potatoes that are still in the ground should be lifted and stored as soon as possible, especially if there is any danger of a second growth taking place.—E. HOBDAY.

Cottagers' Gardens.

The principal operations to which attention should now be directed are the protecting of Grapes and the gathering of fruit. The Grapes, which should now be swelling fast, had better be put into small gauze bags, to preserve them from the attacks of wasps, &c., which are now troublesome. With regard to the gathering of fruit, such as Apples and Pears—the sorts that cottagers generally cultivate—great care is necessary to keep them from being bruised. They should be handled like eggs, in order to ensure their keeping. The time when the fruit is ready for gathering is indicated by its beginning to drop of its own accord from the trees, by its parting freely from the stem on being slightly moved, or if, on cutting open one of the fruit, the seeds are of a dark brown colour, it is fit for gathering. In performing this operation, however, the fruit should never be shaken from the trees, as is often done, but it should be all hand-picked on a dry day. In storing it, let it be taken from the basket, and placed where it is to remain with great care; and, if possible, let it be arranged side by side, and not placed one upon another. With respect to vegetables, look over the seed beds, and keep them clear of weeds. Onions, if not already done, should now be dried and stored as soon as possible, in order that the ground may be got ready for other crops. In flower borders, scarlet Pelargoniums are still in fine condition, and I have lately seen in the open ground some noble bushes of Fuchsia Riccartoni loaded with blossoms. This is an excellent border variety; it is a very profuse bloomer, and may be easily kept over winter by covering the root with a little litter or leaf-mould, so as to keep out frost. Herbaceous plants that have done flowering should be cut down, and have their stems removed whenever they become unsightly. Dahlias, on the contrary, still in bloom, should be trimmed and tied up. If the ground is weedy, run the hoe through it, and endeavour to keep the whole as neat and clean as possible.—J. G.

Proposed Opening of Lincoln's Inn Gardens.—A memorial, signed by the clergy, district visitors, and tradesmen of the locality, has been presented to the Benchers of the Society of Lincoln's Inn, praying that body to be pleased to take steps for the withdrawal of the restriction as to access to the Lincoln's Inn Gardens to the general public, and follow the example of the Benchers of the Temple, to throw open the same at stated hours as a place of public recreation. The memorialists draw attention to the fact that, with the exception of the Temple Gardens, there is no open space within the radius of over a mile where the denizens of the crowded courts and alleys surrounding Lincoln's Inn Fields have an opportunity of getting a breath of pure air. The memorialists further urge, that whatever the cost may be, of keeping the gardens in efficient supervision, they consider it should be paid by the Metropolitan Board of Works, and a memorial to that effect would be presented to that body in due course. Lincoln's Inn Fields is the finest city garden in London, and we trust it may speedily be opened to the public. A little good taste, and, say one-twentieth of the sum spent on Leicester Square, would make a garden of Lincoln's Inn Fields of which London might be proud. The trees are already superb; it only remains to dispose

of the turf and ground in a graceful manner, to remove the miserable decaying shrubs which are massed inside the railings (as is the too common practice in London squares), to plant, with thorough preparation, the trees and shrubs that will thrive in the situation, and lastly, and chiefly, to keep out the architect, sculptor, mason, stucco-man, and the rest of them, and see how much could be done in Lincoln's Inn without their aid.

SOCIETIES AND EXHIBITIONS.

AUTUMN EXHIBITION AT THE CRYSTAL PALACE.

THIS exhibition shows a great falling off from those held in previous years, neither flowers nor fruit being well represented. Grapes and Pines were, in one or two cases, of splendid quality, especially those staged by Mr. Coleman. Mr. Potts, and Messrs. Lane & Sons, who had fine clusters of Muscats, for which they are deservedly famous. Superb Pines came from the Royal gardens, Frogmore, and Mr. T. Bond had a good Queen, which was only 2 ozs. short of 7 lbs. The classes for Gladioli were not so well contested as usual, but excellent stands came from Messrs. Kelway & Son, Mr. J. Douglas, of Loxford, and the Rev. H. H. Dombrain, the flowers being in fair condition for the season. Mr. Charles Turner, of Slough, staged a collection of Show, Fancy, and Pomponé Dahlias, not for competition, to which an extra prize was awarded. Mr. H. Coppin, Rose Nurseries, Shirley, Croydon, sent a nice stand of cut Roses, to which a similar award was made. Messrs. Downie, Laird, & Laing, of Forest Hill, sent a charming group of dwarf Palms and ornamental foliage plants, which deservedly obtained an extra prize.

Fruit.—Excellent collections came from Mr. W. Coleman, gardener to Earl Somers, Ledbury, and Mr. Bannerman, gardener to Lord Bagot, Rugby. The first named exhibitor had a good Queen Pine, Black Hamburgh and Muscat Grapes, Victory of Bath (Gilbert) Melon, Peaches, Nectarines, and an excellent dish of brown Turkey Figs. Mr. J. Deuxberry, Mr. Neighbour, and Mr. O. Goldsmith, also obtained prizes for fair collections. The best Pines came from Mr. T. Jones, of Frogmore, who had four fine smooth Cayennes. Mr. J. Coulter, gardener to E. J. Baker, Esq., Haydon Hall, Pinner, was second with excellent fruit of the same variety, Mr. R. Plummer being a good third. Mr. T. Bond, gardener to G. A. Smith, Esq., The Beeches, Weybridge, was first with a Queen Pine, the weight of which we have already given. The Veitchian fruit exhibition at South Kensington showed what good prizes will do, and it is useless to expect gentlemen or gardeners to cut their best fruit when it is worth at least twice the sum offered as a prize. Large clusters of Black Hamburgh came from Mr. Coleman, who deservedly took the first award. Mr. Potts, gardener to Sam. Mendel, Esq., Manley Hall, near Manchester, was second with good examples of Madresfield Court. Messrs. Lane & Son were first for Muscats, while those staged by Mr. Coleman, although by no means so fine, had the advantage in being more perfectly ripe and better finished. Mr. Cole, of Ealing Park, had large berried clusters, and took the third award. The prize for the heaviest bunch fell to Mr. Bones, who had a double cluster of Black Hamburgh, weighing 5½ pounds. Mr. Bannerman was second with Gros Guillaume (Barbarosa), and Mr. Earp, gardener to J. S. Sellow, Esq., Hume Towers, Bournemouth, was third with a cluster of Black Alicante weighing nearly 4 pounds. Peaches were very poor, the prizes going to Barrington, staged by Mr. Coleman; Bellegarde from Mr. Bannerman; and Wallburton Admirable from Mr. Holliday. Mr. Goldsmith took first award for Pittamaston Orange Nectarine, Mr. Coleman being second with Violette Hâtive, and Mr. W. Gordon was third with smaller specimens of the last named variety. The first prize offered for Melons went to Mr. C. J. Goldsmith, who had Golden Queen. Mr. J. Mayall was second, with a good Victory of Bath (Gilbert); Mr. Churl, of Clarendon Park, Salisbury, being third with Incomparable. Apples were rather below the usual average, but the classes were well contested. For a collection of four dishes, R. Webb, Esq., of Reading, was first with Cox's Orange Pippin, Ribston Pippin, Red Astrachan, and Devonshire Quarrenden. Mr. Holder, gardener to W. Balston, Esq., Maidstone, was second, with Golden and Cox's Orange Pippins, Margaret and Kerry Pippins, both well coloured. Mr. A. Longman, gardener, to E. Lushington, Esq., Maidstone, was third. Kitchen Apples were staged by Mr. Swinnerton, Swanley, Sutton-on-Hone; Mr. Chaff, gardener to Charles Goschen, Esq., Addington, Croydon; and Mr. H. Mandy, the prizes being awarded in the order named. Pears were well represented, the three best dishes coming from P. Gosset, Esq., of St. Saviour's, Jersey. These consisted of Louise Bonne, De Coq, and Bon Chrétien (Williams's). Mr. W. Strong, gardener to H. Yool, Esq., also had good examples of Louise Bonne and Williams's Bon Chrétien. Mr. Jordan had a splendid dish of Grosse Calbasse, weighing nearly 10 pounds; and Mr. Stephenson had a good dish of Beurre Clairgeau in the same class. The prizes offered for flavour went to Louise Bonne, from Mr. Strong, while Mr. Sage and Mr. J. Lane were second and third respectively, with Beurre d'Amanhis and Williams's Bon Chrétien. Plums were of excellent quality, although the number of exhibitors was rather limited. Mr. Coleman takes the first prize, with fine fruit of White Magnum Bonum, Washington, and Jefferson; Mr. Pitts and Mr. Deuxberry being second and third in the order named. A dish of Cherries came from Mr. A. Parsons, Danesbury Gardens, and Mr. O. Goldsmith and Mr. J. Holder were second and third, with fine Morellos. Mr. W. Chisholm, gardener

to R. C. Taylor, Esq., of Broughton Place, Maidstone, was first for a dish of Brunswick Figs; Mr. H. Mandy and Mr. Coleman being respectively second and third, with White Ischia and Brown Turkey. Messrs. Lane & Sons staged fruiting Vines, in pots, to which a first prize was awarded, and Mr. Webb, of Calcot Gardens, near Reading, staged a fine collection of Filberts and Cob Nuts, to which an extra award was made.

Certificates were awarded by the Judges to the following novelties:—

Apple Peasgood's Nonesuch (Brown & Co.).—A fine fruit, either for kitchen or dessert use, and well worth general culture.

Gladiolus Mr. Wilson (Kelway).—A deep lilac-purple flower, flaked with crimson; good spike.

Gladiolus Duchess of Edinburgh (Kelway).—A robust variety, with immense flowers arranged on a stout spike. The colour is rosy-purple, with a white purple striped centre.

Gladiolus La Véruve (Dombrain).—A fine robust variety, bearing a spike of glowing scarlet flowers, the centre of the segments being inclined to white.

Gladiolus Manfred (Douglas).—A bright orange-scarlet flower, of good substance.

Gladiolus Warrior (Douglas).—A bright scarlet flower, flaked with white.

Dahlias Rob Roy, Pollie, and Warrior (Turner).

THE CITY MULBERRY TREES.

DEGENERATE Drapers! Is it a fact

That the utilitarian cataract

Your eyes has so served to harden,

That you really mean, for a paltry fee,

To disestablish the Mulberry Tree—

Grub up your lovely garden?

A glimpse of green in the City's heart!

A little haven of rest apart

From Mammon's turmoil and trouble!

Pshaw! L.S.D. is the faith we hold

Build over the front with its fish of gold,

So our rental of gold we double.

'Tis the God of the Age, this L.S.D.—

The utilitarian trinity—

Whereof we are all adorers:

And a City Company's bound by its creed

To stick right close to the friend in need,

And scorn sentimental soarers.

So the Mulberry Trees are all laid low,

And there's an end to their golden glow—

The brighter that seemed for its rarity;

And may we ask—or were't better not?—

When the garden is gone and the money is got,

Will it be spent in Charity?

Or will it be spent, City-Company-wise,

In making each dinner a new emprise

For digestion's taxed activity?

What's a fountain fair to a turtle tureen,

Or the greenest lawn to the fat that's green

At a gorgeous Hall-festivity?

For this indeed did our Fathers build?

Was gutting and gorging of each old Guild

The end, if not the beginner?

Did they dream those Mulberry Trees must stop

To furnish a little more turtle-soup

At the Drapers' magnificent dinner?

Punch throweth not. In those ages old

They feasted well upon well-worn gold,

And of charity were not chary:

They lived great lives, and helped their neighbours,

And this was the motto of their labours,

L'hoi-care est arce.

A dinner is good, saith the Prophet *Punch*,

If not too greedily people munch:

But the diners and money-scrappers

Might feel that a spot of garden-soil,

In the very heart of the City of Toil,

Should have sacred been kept by the Drapers.

—*Punch.*

Too good to be true.—M. Paraf is said to be the discoverer of a way of doing without rain, if necessary. He knew that the air is full of moisture, and he knew that chloride of calcium would attract and condense it, for cultural purposes. He has applied this chloride on sand-hills and road-beds, on Grass, on all sorts of soil successfully, and he has ascertained that it may be applied in such proportions as will produce the irrigation of land more cheaply and efficiently than by means of canals or other methods of securing artificial irrigation. One of M. Paraf's applications will produce and retain abundant moisture for three days, when the same amount of water introduced by the present method will evaporate in an hour. M. Paraf states that he believes that his preparation will not only produce two blades of Grass where but one now grows, but that it will render possible fields, meadows, and prosperity, where now there is nothing but sand and desert waste.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

PLANTING TO PRODUCE LANDSCAPE EFFECTS.

By JAMES M'NAB, Botanic Gardens, Edinburgh.

PLANTING for landscape effect requires much thought and consideration, and, even with all the care that can possibly be bestowed, it is often extremely difficult to bring out, in an effective manner, the ideas which one is anxious to secure, particularly while operating on a piece of ground newly laid out, and previously unplanted; but with partially planted lands, landscape effects are more readily obtained. On perfectly level ground difficulties often occur which on undulated or sloping surfaces, are more easily overcome. Lands which have been long laid out and well planted, but without any arrangement as to landscape effects, may, in most cases, be looked upon by the casual observer as perfect in their way, while the practised eye of the landscape gardener will pick out many blemishes, and be able to suggest improvements. A change may rapidly be effected if one is empowered by the proprietor with entire control, to root out unsightly and duplicate specimens for the purpose of making clearances, at the same time to bring more prominently into sight some distant trees possessing colour and outline which hitherto had been entirely excluded from view, and here and there planting others of such a nature as will harmonise with those already existing. A great diversity of colour and outline is to be found in the forest and ornamental tree department of all our nursery establishments, but the art of grouping and arranging the various species in the park and pleasure grounds, requires quite as much skill and perception as is generally employed by a landscape painter, so as to have his picture well balanced, at the same time to blend the colours so as to make it pleasing to the eye. When arranging trees for landscape purposes, it should be done, as much as possible, so as to produce effects suitable for spring, summer, autumn, and winter—evergreen trees, such as evergreen Oaks, Hollies, Yews, and Pines, being employed for the latter purpose. It cannot be expected that every portion of a large property can be arranged equally well, but some parts may be improved by judicious grouping or planting in masses, taking care to have undulating edges instead of straight ones, which too frequently prove hard to the eye. It is quite possible to have portions here and there artistically grouped, and, in time, the intermediate spaces can be filled up with fitting trees. Any landscape effects aimed at, ought to be made to tell from the windows of the mansion-house, or carriage-drive, or from some favourite seat or walk, in the neighbourhood of an artificial lake or pond, taking care, in all cases, to select a good and somewhat distanced background of thick-foliaged trees, as Sycamores, Elms, Limes, Oaks, &c. Occasionally a few Lombardy Poplars will be found telling objects in the landscape, provided they are kept at a distance, and confined to one point—a number of such trees, irregularly dotted about, being anything but pleasing. It is absolutely necessary to remove the tops of Lombardy Poplars, after they have fairly taken to the ground, leaving stems about 4 or 5 feet in height. Numerous leaders will then be produced from the sides of the portion left, and all will be found to assume an upright habit, and in this condition will stand the wind well. Thousands of these now planted throughout the country, assume a free upright habit at once, and although 10 feet in height, leaves are often only seen at the lower part of their stems, or on their summits, the intermediate side branches being often dead; this is probably caused through wind waving, an occurrence to which they are often subjected, and which has a tendency to throw the sap entirely to the top. If cut down, even at an advanced stage, they will break out again, and make good specimens, thoroughly clothed all over. Other upright trees, as Thorns (*Cratægus Oxyacantha fastigiata*), Oaks (as *Quercus pyramidalis* and *Q. fastigiata*), and Elms (*Ulmus fasti-*

giata), will also be found useful for intermediate spaces; and, although a better class of upright trees than the Lombardy Poplar, and equally effective, they should be sparingly used. Weeping trees, such as the varieties of Birch, Elm, Ash, Lime, Willow, Aspen Poplar, Beech, &c., are also very effective, and one or two of each may, now and then, be introduced with considerable advantage—particularly the Birch, its white papery bark being often very telling. In contrast to the foliage of the ordinary dark green trees, a Larch or two coming in contact with them during early spring is often truly beautiful; at the same period the Corstorphine Plane also gives variety to the landscape. When its foliage first appears, it is of a rich golden tint, which continues for some time; but, as the season advances, it assumes the ordinary green hue, and, when standing free, the outline of its top is exquisite. The Golden-leaved Thorn also comes out in spring with a rich yellow hue, which tells admirably, and forms a beautiful contrast against dark-foliaged trees; but, afterwards, it returns to the green colour. Rich spring effects, although often of short duration, but in interesting succession, are also produced by the colours of the flowers of many trees, such as the Horse Chestnuts, Thorns of different sorts, Guignes, Bird Cherries, double-flowering Cherries, Laburnums, flowering Ash, &c. Further on in summer, all the permanent variegated and coloured-leaved trees are exceedingly pleasing when judiciously blended amongst the ordinary green-coloured ones. Of the former, I may mention the variegated Elms, Oaks, Ash, Acer, Thorns, &c.; and, of coloured leaves, the purple Beech, Hazel, red-leaved Acer, golden-leaved Oak (*Quercus concordia*), also the *Pyrus nivalis*, and the white-leaved Willow, particularly the *Salix Regiæ*. *Populus nivea* and *Sorbus vestita* are also interesting on account of their leaves being dark green above and white beneath, thus presenting a singular effect during a slight breeze. Specimens of *Populus nivea*, although useful for landscape effects, are often greatly damaged by wind, on account of the brittle nature of their spreading branches. If well cut or pruned in during their young state, they will afterwards be found to stand the wind better, and become more shapely objects, than when left entirely to themselves. A great diversity is often produced by some of the trees with narrow or peculiar leaves, such as the Fern-leaved Beech, Fern-leaved Elm, cut-leaved Lime, Willow-leaved Oak, and others. Numerous species of trees contribute largely to autumnal effects, the depth of this depending in a great measure on the wood being thoroughly ripened during the previous summer. The Beech, Thorns, Liquidamber, Sugar Maple, and American Oaks, produce more or less the red or scarlet hues, while the *Sorbus*, Birch, Lime, *Pavia flava*, &c., give a yellow tinge. Of fruit-bearing trees, the Mountain Ash and Thorn are the most conspicuous. The various species and varieties of the Service tree (*Sorbus domestica*), are also interesting when in fruit. The fruits, however, no sooner come to maturity than they are cleared off by birds. The Scotch Laburnum (*Cytisus alpinus*) at one time, when its leaves begin to assume the yellow tinge, likewise when covered with fruit, when placed in various positions, is often seen to present a remarkable and rich effect when fully exposed to the rising and setting sun, the pods appearing like golden flowers, particularly when backed by any of our dark-foliaged trees. In most cases, deciduous trees, planted for effect, should stand on Grass, or in clumps with more or less Grass lawn between each. Although this paper gives a tolerable list of trees suitable for landscape purposes, it is far from being complete; too many of one kind in one place, when fully matured, will take away from the effect aimed at. To do this work properly, several plants of some of the kinds may be introduced at first in various places, but removed in time, so as not to interfere with good outlined specimens, planted for pure landscape effects. The great Coniferous group, which now amounts to upwards of 500 species and varieties; of all forms and sizes; of all tints, from the darkest green to rich gold and silver hues, as well as endless variegations, including the various phases which many of the species undergo during the summer, autumn, and winter months, is sufficient of itself to furnish many interesting landscape effects; the dark hue of many of the Pines, forming the background, while the drooping, upright, and coloured varieties, are admirably adapted for intermediate and foreground positions.

NOTES OF THE WEEK.

— WILL no one bring to our market the luscious Water Melons of the south and the west? The small and wretched specimens now in Covent Garden have nothing in common with the true species, which we have never seen in perfection in England. Good Water Melons taste not only of water, but have a delicious flavour, and are almost as bright inside as a blown Rose. We read that one steamer brought 40,000 of them to Boston from one of the more southern states last week. They are sometimes nearly 40 lbs. weight in America, and do quite as well in many parts round the Mediterranean basin.

— THE beautiful, large, and fragrant single Japanese Rose (*Rosa rugosa alba*) has been sent us in fine bloom by Mr. Ware, in whose nurseries, at Tottenham, it is now in flower. It is one of the many single Roses which deserve a place in every garden. The white of the large flowers, opening one by one, is as pure as that of any flower in existence, and the dark green closely-pinnate shining leaves are very ornamental.

— THE freeholder of an almost unknown garden, that in Golden Square, is going to perform a task similar to that of Mr. Albert Grant. This is really a capital movement, which we hope will spread. Of course, there are many of our squares which are to all intents and purposes the private gardens—and the only ones—of the residents, and nobody wishes to interfere with them; but there must be from fifty to a hundred of those enclosures, which are of no use to anyone at present, and might be splendidly utilised as play-grounds for the people, and additional lungs for London.

— BOTH the crimson and white varieties of *Lapageria* are now flowering profusely in a cool corridor in Messrs. Veitch's Nursery at Chelsea, the white flowers mingling with the crimson ones, and producing a charming contrast. Both plants never look better than when planted out in a moist border of peat in a cool and partly-shaded greenhouse or conservatory, in which they are permitted to spread under the roof in a somewhat natural manner. Treated in this way, and liberally supplied with moisture, they grow vigorously, and, as in the case in question, produce hundreds of flowers of both colours, in pleasing yet striking combination.

— IN the *Graphic* of last week is a representation of Anderson's Mummy Pea, a variety apparently identical with Grimston's, about which so much was said some years ago. The latter was considered to be the old Branching Marrow. The stalk of this Egyptian Pea is said to be peculiar. Near the ground it is attenuated, but at the summit it is several sizes thicker, so that it appears a necessity to support it, and the more so as the pods are also clustered together at the head of the plant, instead of being, like the ordinary Peas, distributed along the stalk. Though not pleasant in flavour, these Egyptian Peas are eatable; they resemble grey field Peas. We do not, however, believe in the "mummy" origin of this Pea.

— SPEAKING of the Wellingtonia, Mr. Robert Hutchison, of Carlewrie, says: "The soil and climate of Ireland seem to be peculiarly well adapted for the Wellingtonia, and many instances might be recorded of very handsome and thriving specimens of it occurring in various districts of that country. One in particular is perhaps deserving of special notice here, as being probably at the present time the tallest specimen in the United Kingdom; I refer to the tree at Cecil, county Tyrone, which, although only planted fourteen years ago, is already about 45 feet in height, and growing luxuriantly." From our own observations we should say that Southern England was more suitable for this tree than Ireland. There are certainly taller trees in England than the one in Tyrone.

— AN *American Garden* (monthly) has been started in Brooklyn; it is edited by Mr. Hogg, a well-known and able horticulturist of English descent. He remarks, in the first number, that "unfortunately for the art of gardening in America, the journals are, however, for the most part, filled with extracts from foreign papers. The practices therein recommended, owing to differences of climate and other reasons, are not adapted to our necessities, and can only be made useful by the valuable hints and suggestions which they convey to persons of otherwise large experience. On the other hand, the articles of home production are generally the work of persons whose reading and practice have been too limited to afford the qualifications needful for giving instruction. Hence, too often, they contain that which is empirical and exploded in practice, and, not unfrequently, lead those who adopt their suggestions to grievous disappointment. There are, in all the country, but four periodicals which are devoted exclusively to horticultural and floricultural objects; and two of these confine their attention, mainly, to the interests of professional men, and have but little circulation in the larger circle of amateurs." We do not acknowledge the force of these observations in full, as much of the horticultural and rural literature of America is remarkable for complete knowledge of the subject, lucidity and point in

expressing that knowledge, and not unfrequently for an abundance of excellent illustrations which make the writers' meaning on every point clear at a glance. Mr. Hogg is a horticulturist of much taste, and we hope his new paper may live and advance the art in the New World.

— THE finest of all blue conservatory wall or pillar plants, *Plumbago capensis*, is now flowering freely as an edging-plant in the London parks.

— *ONCIDIUM ZEBRINUM* is now in flower in Mr. Salt's fine collection of cool Orchids, at Fernhurst; its spike is 10 feet in length, profusely branched, and bearing in all 240 flowers, each measuring half or three-quarters of an inch in diameter.

— *TRITOMA MACOWANI*, a new species, is just now in flower in a cool house at Kew. It is in a pot, and owing to its dwarf habit, it seems well-suited for pot-culture. Its blooms are of a paler colour than those of the commonly grown *T. Uvaria*.

— AT the Botanic Garden, Oxford, the Mexican *Dasylicion arcotrichum* recently threw up a flower-stem which, when 12 feet high, grew at the rate of 6 inches in twenty-four hours. The *Nelumbium speciosum* (the Sacred Bean) is reported this season as producing perfect seeds.

— *Galignani* states that the vintage has commenced in the different Vineyards of the Orleanais, and gives excellent results. The wine is expected to be of good quality, and in certain places will realise in quantity more than the cultivators expected.

— WE have received from Messrs. Lamoureux & Co., of Plymouth, specimens of their new hybrid *Amarantus Henderi*. It is the result of a cross effected between *A. elegantissimus* and *A. salicifolius*. The plants grow about 18 inches or 2 feet in height, and form perfect pyramids of rich orange, rosy-carmine, and bright green foliage.

— A PLANT of the white-flowered *Maxillaria grandiflora* is now in bloom in Messrs. Low's nursery, at Clapton. In habit it is something like *M. venusta*, but bears much larger snow-white long-petalled flowers, the lips of which are stained with lemon-yellow and streaked with deep chocolate beneath. It is a beautiful Orchid, rarely seen in collections.

— ONE of the many valuable results of the work of the United States Geological Survey of the Territories, is a "Synopsis of the Flora of Colorado," by T. C. Porter and J. M. Coulter. It is a very interesting region to the plant lover, and we hope the work may bring the knowledge of the subjects down to the latest explorations.

— CONSPICUOUS among rock or border plants in bloom at the present time, is *Pentstemon breviflorus*, a distinct yellow-flowered species, with foliage resembling that of the narrow-leaved Myrtle. It forms a neat dwarf bush, which, viewed from a distance, looks like a dwarf species of St. John's Wort. This plant may now be seen in flower at the Hale Farm Nursery, Tottenham.

— THE fine collection of Orchids, formed at Farnham Castle, by the late Bishop Sumner, was sold this week at Stevens'. For one of the most remarkable plants which it contained, viz., *Dendrochilum filiforme*, £25 is. was obtained, and a fine plant of *D. glumaceum* realised £143s. 6d. A plant of *Angraecum eburneum superbum*, which, last year, bore sixty-four blooms on five spikes, fetched £213s. Others brought from £3 to £10 per lot.

— AMONG the most attractive plants in the Gardens of the Royal Horticultural Society at South Kensington, are the Hydrangeas, which are now in full flower. They succeed well planted out in the shrubbery borders, and flower profusely every autumn. In some parts of England and Ireland, near the coast, the Hydrangea is one of the finest of all summer and autumn flowering shrubs, often forming specimens 30 or 40 feet in circumference and 6 or 8 feet in height. In many of the southern counties the Hydrangea also grows well, planted in clumps or masses on the margins of walks and shrubbery borders, and if cut down during exceptionally severe winters, it rarely fails to push up from the root the following spring.

— SOME of our contemporaries are afraid that if Trafalgar Square were to be laid out as a garden, it would soon lose its freshness and beauty. No fear need be entertained on this head, however, if the work be carried out by a practical landscape gardener, who understands the beautifying of city spaces, and comprehends the use of the wealth of vegetation which will succeed in such situations. We could point to lawns in many town gardens as fresh and as green as any in country districts, while the choice of trees, need not, by any means, be limited to Planes alone, although, undoubtedly, the Plane is the finest of all town trees. The Temple Gardens are in a far worse neighbourhood than Trafalgar Square, yet, here we have fine Catalpas, Poplars, and other trees, and as fresh a breadth of cool green turf as anyone could desire; while here we have been taught how to get a glimpse of bright colour and floral beauty in city gardens even during the dullest part of the year.

THE FRUIT GARDEN.

SMALL VERSUS LARGE POTS FOR PINES.

In answer to "A Pine Grower's" remarks (see p. 244), I have only to say that the system of growing Pines in small pots is one fairly established here, and, therefore, my statements in reference to it cannot be regarded as "wholly unsupported either by theory or practice." We sometimes cut two dozen fruit here in one day, and we find that those cut from plants grown in 10-inch pots invariably outweigh a corresponding number cut from plants in 12-inch pots. One important consideration with regard to Pine plants in small pots is the readiness with which they can be got to fruit—a difficult matter with many. Pine growers, as a rule, like fine-looking plants; but, from such stock, fruit is seldom obtained when desired, and when it does come it is hardly ever proportionate in size to that of the plant which produced it. Vigour, to a certain extent, is all very well; but, too much luxuriance is a mistake, a remark which also holds good in the case of Vines, and other fruit-bearing plants which might readily be named. Strong spongy wood, which looks delightfully vigorous, is seldom productive of good results; nothing surpasses firm sturdy growth, of moderate strength, as far as fruitfulness is concerned. Your correspondent speaks of the smooth Cayenne as being a more robust grower than the Queen, and as producing proportionately larger fruits. The stronger growth has, however, nothing to do with the difference in the size of the fruit; it is natural for the one to have smaller fruit than the other. With us, plants of the Queen variety are always stronger, and have more foliage than those of the smooth Cayenne, while the fruit of the former is the smallest. It is precisely the same with the Duchess of Buecleugh Grape, and Gros Coleman. The Duchess is much the stronger grower of the two, and yet the fruit is not half the size of that of Gros Coleman. In selecting large Pine suckers, there is an advantage, inasmuch as the plants sooner get large, than would otherwise be the case, and sometimes they fruit earlier; but I never found the fruit of such plants to be larger than that obtained from plants of which small suckers were originally used. We have a seedling Pine here, which promises to be an improvement on many kinds in cultivation. Corpulent, well-shaped fruits of it, now swelling in 9-inch pots, are already bordering on 4 pounds each; yet the plants have few leaves, the whole (with the exception of the crown) on one plant, which is producing the largest fruit, numbering fourteen. In this case, the secret chiefly lies in the 9-inch pot, which is full of splendid roots, the energies of which are not spent in sustaining a mass of hungry leaves, but, on the contrary, go to support the fruit. "A Pine Grower" remarks that the Providence is a stronger grower than either the Cayenne or Queen, and that it produces the largest fruit of all (?). Lambton Castle Seedling has fewer leaves than any of the three, and yet its fruit is the largest. Pines, now-a-days, are fruited in half the time they used to be years ago; and to what cause may this be assigned? Mainly to the smaller-sized pots in which they are now grown; temperature, soil, and general treatment, being much the same then as now. If we were to revert to the huge pots in which Pines were formerly grown, fruiting would only occur once in three or four years; while the plants themselves would be tall enough to push up the sashes of a 3-feet deep frame.

I have in my time seen abundance of plants of this kind, which would doubtless have gladdened the heart of "A Pine Grower;" but, as to fruits, alas! where were they? "The mere assertion that So-and-So grows his Pines in 10-inch pots conveys no meaning." This may be the opinion of some; but the fact that So-and-So grows his Pines better in 10-inch pots than other Pine growers do in 12, 14, or 16-inch ones is a matter well worth consideration. Your correspondent says he "has an impression" that I refer to some kind of 10-inch pot which holds as much soil as a 13-inch one. I am, however, unacquainted with such pots; indeed, I may say that I have found the pots to correspond with the figures both in England and Scotland. The pots in which we grow Queens have an inside width at top of 9 inches, at bottom of 5 inches, and in depth they are 9 inches. For smooth-leaved Cayennes and the strong-growing sorts we

use pots 10 inches in width at top, 6 inches at bottom, and 10 inches in depth. I consider a 4lb. Pine large enough, and a size most serviceable for any purpose. Your correspondent seems disposed to disparage market-grown Pines when he says, "it may be better for market purposes to grow more plants and to have a greater number of fruits;" but to this I would answer, what takes in the market is pretty sure to pass unquestioned elsewhere. This is fully confirmed by the fact that many Pines cultivated by market gardeners find their way to the tables of those who grow Pine plants themselves. Two feet apart is sufficient for Pines grown in 10-inch pots, either with or without Vines, or any other dense covering overhead. When Vines are grown overhead it is still more necessary, than when they are grown otherwise, to confine the Pine roots to small pots in order to ensure fruitfulness, and to prevent the plants from getting too much elongated.

Clovenfords.

J. MUIR.

IMPORTANCE OF A GOOD SUPPLY OF WATER.

The long continued drought, which I trust may now be considered to be at an end, should induce us to look to our late supplies in order that we may be better able to prevent failures in future. I may safely assert that we have given artificial watering a fair trial, and the result is that fruits of all kinds are far above the average; vegetables, too, are of excellent quality; and our floral display is all that could be desired; for brilliant sunshine and a clear dry atmosphere have brought out the different colours in perfection. Foliage plants enjoy, immensely, a short spell of tropical weather, provided their roots are kept moist by mulching and frequent delugings of water. The damping system destroys more plants than even drought unchecked, as watering the surface draws the roots upwards, and the first scorching day completely roasts them, and the plants droop and wither. If proof were wanted that artificial irrigation may be successfully carried out in its entirety, so as to render our gardens independent of the annual rainfall, I would at once point to the triumphs of horticulturists under glass, where an entirely artificial system of watering produces fruits and flowers in perfection. In fact, such a season as the past, with plenty of sunshine, gives us better flavoured and more highly coloured fruits than our usually dull dripping seasons do. Whoever heard of fruits under glass roasting on the trees owing to too much heat, and being small and tasteless, even though they get all the extra heat that glass structures can afford them? The fact is, it is more a question of labour and expenditure than one of skilful culture; the staff of most gardens would require to be doubled before it can be hoped that fruit culture on walls and open quarters will come up to that under glass. When fruit tree borders have been well mulched and soaked with alternate applications of liquid manure and clear water, and the garden engine is kept at work so as to keep the first growth in health and vigour, no fears need be entertained as to the ripening of either fruits or "bearing wood for another year," both important points in fruit culture. On the other hand, during a dry summer, when the trees have to struggle for existence, when autumn rains come, they encourage a rank immature growth, the bloom buds on which are imperfectly developed, and the consequence is failure as regards a crop of fruit. Let us, therefore, before it is too late, look to our water supplies.

JAMES GROOM.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Early Grapes: H. K. S. To ripen Grapes in May, you should start your Vines in November. Your house may not be so light as could be desired, but there is nothing to hinder you from forcing the Grapes as you wish and having them ripe in May. It is desirable to do all early forcing in well-heated and not over large houses.

What Constitutes a Dish of Fruit for Exhibition: H. S. The standard for quantity comprising a dish of fruit for exhibition, as given by the Royal Horticultural Society, is of Grapes three bunches, of Apples, Pears, Peaches, Nectarines, Figs, &c., six fruits; of Strawberries, Cherries, &c., generally fifty fruits.

Pruning Newly-planted Fruit Trees.—Am I right in pruning fruit trees as soon as planted?—W. F. [Young fruit trees pruned back at the time of planting do not succeed so well as those which are left unpruned until the sap commences to move in the spring. Then you can see better the state of the young tree, which will not suffer so much as if it had been pruned soon after being disturbed in the planting.]

THE LIBRARY.

VAN HOUTTE'S FLORE DES SERRES.

THE first quarter of the twentieth volume of this work has at last reached us (many months after it was promised, as usual), and we are sorry to say that it is inferior in interest to any triple part of the work which we have yet seen. It would be more satisfactory if Mr. Van Houtte would desist as much as possible from copying plates from other works, and occupy his space with original plates (which his establishment is well able to produce) of the many fine novelties introduced by his own travellers, and those of other foreign houses, especially in the way of new hardy flowering shrubs, which are not nearly as much or as widely known as they deserve to be, and which well executed portraits appearing in such a work would do much to popularise. The part commences with four well executed double plates of Pears, each containing some twelve or thirteen kinds of these fine fruits, but however interesting these may be to pomologists, we cannot but consider them totally and entirely out of place, and inappropriate for such a purely horticultural work as the "Flores des Serres" professes to be. If Mr. Van Houtte wishes to illustrate these fruits, how much better would it be to publish the plates in a separate or supplementary form, so that those who did not want them, need not have them bound up with their volume, which cannot now be done without rendering the letter-press of the volume incomplete. Plate 9 is a beautifully executed portrait of a lovely bulbous plant from the Andes Mountains, named *Placa ornata*; as it is found in its native mountains at an altitude of 8,000 yards above the sea, it would, in all probability, be quite hardy wherever the Belladonna Lily is able to withstand our winters, or require at most a few inches of litter or ashes to protect the bulbs from severe frosts. The flowers are creamy white, deeply lined with carmine streaks, and are borne, like those of the Belladonna, in umbels of from eight to ten on the top of a tall stalk. Plates 10 and 11 represent one of the handsome foliage plants recently introduced from Brazil, under the name of *Calathea* or *Maranta Makoyana*.

Plates 12, 13, 14, 15, 16, 17, and the woodcuts and letter-press on the intervening pages, are a translated condensation of Messrs. Moore and Jackman's work on the Clematis. The varieties figured in the coloured plates are *Rubella* and *Marmorata*—the former well-known, and the latter a dull and poor variety of little or no interest; *Viticella rubra grandiflora*, a small dull deepish-red variety; and Mrs. James Buteman, a fair-sized flower of a purplish-lilac colour, not much to be admired; and Messrs. Cripp's fine double variety, somewhat resembling a deep-coloured form of John Gould Veitch, which they have named *Excelsior*. Plates 18 and 19 are a reproduction of Messrs. Fröbel's plate of *Begonia octopetala*, sent to them by M. Roezl from the Andes Mountains, and re-introduced by them to European gardens after having been lost to them since 1837, when it was flowered in the Glasgow Botanic Gardens in the stove, which treatment was in all probability the cause of all the tubers perishing. The plate was prepared by M. Fröbel from descriptions sent to him with the tubers; but certainly is not, by any means, a faithful representation of the flower as produced from a tuber received from M. Fröbel, and flowered in the open air by one of our correspondents in the south of Ireland, who informs us that the flowers produced by his plant are quite a size smaller than those in the plate, and entirely without the deep rose-coloured underpetal, which adds so much to the beauty of the flower as figured by M. Fröbel. The flower, in reality, much resembles a small white *Anemone japonica*, of a duller shade of colour than that fine hardy perennial, and is quite correctly figured in the *Botanical Magazine*, Vol. LXIV., tab. 3,559, from the specimens flowered at Glasgow in 1836. Plate 20 represents the beautiful *Odontoglossum vexillarium*, so finely figured in Mr. Bateman's "Monograph" of this family, and also in the *Floral Magazine* by Mr. W. G. Smith. Plates 21 and 22 faithfully represent those two beautiful and almost hardy climbers *Lapageria rosea* and its snow-white variety, than which two more beautiful or valuable plants (as they produce their lovely flowers usually all through the dull winter months) could not be trained to the trellis of a conservatory. Plates 23 and 24 are a reproduction of the fine plate of *Lilium Kraueri*, given in last year's volume of the *Botanical Magazine*, tab. 6,058, from a specimen furnished by G. F. Wilson, Esq., of Weybridge. Plate 25 represents *Sarracenia Psittacina*, a dwarf low-growing rosy-tipped variety of this family from Georgia. Plates 26 and 27 represent *Cypripedium japonicum*, a fine new hardy species of Lady's Slipper, introduced from Japan by Messrs. Teutschel of Colchester, and somewhat resembling the beautiful Canadian variety, *C. spectabile*, the slipper being white streaked with carmine, and the upper petals green, slightly spotted with light brown.

Since the above was in type, we have received the second triple part, completing half the volume, and we are happy to say that it

far exceeds in interest and in the beauty and novelty of the plants figured in the first quarter of the volume. In fact, we may say that with the exception of the concluding four double plates of the number being again occupied by Pears, the plates, generally, equal in interest and beauty, and delicacy of execution and colouring those of any part of the work that has yet come under our notice.

Plate 1 represents very faithfully that fine hardy border plant *Tropæolum polyphyllum*, with its racemes of large bright golden blossoms; this is much less generally grown than it deserves to be. It is a tuberous-rooted perennial species, with conspicuous glaucous foliage, and of a low growing trailing habit of growth, flowering freely when once established in a bed or border about the month of May. Plates 2 and 3 admirably represent a fine addition to our hardy shrubs from the extreme north of Japan, whence a single seed came by chance among some others sent to Dr. Regel by the well-known Russian collector, M. Maximowicz, who sent it unwittingly to Mr. Van Houtte, in whose gardens it germinated in due course, and when inspected by Dr. Regel and Professor Decaisne of Paris, was pronounced by both these learned authorities to be quite a new and unknown variety of the Araliaceous family, and quite distinct from anything already in cultivation. It has been accordingly named after its introducer *Aralia Maximowiczii*, and has been propagated, and is now being distributed, by Mr. Van Houtte. Plates 4 and 5 represent that curious inhabitant of our stoves known under the name of *Mantisia saltatoria*, or Opera Girl, the tremulous upper portions of its flowers somewhat resembling a dancer. It is a native of India, and produces copious heads of flowers of a bluish-lilac shade with a golden lip. Plates 6 and 7 represent a fine seedling *Azalea* raised by Mr. Van Houtte, and named by him John Gould Veitch. This variety much resembles in shape and colour another very fine variety, named *Sigismund Rucker*, also raised by Mr. Van Houtte, and figured in the nineteenth volume of the "Flore," but is said to exceed this variety in the size of the individual blooms; both are exceedingly free flowering. Plates 8 and 9 represent four fine varieties of *Iris Kämpferi* introduced by Von Siebold from Japan, and which bear the names of (1) *Alexandre Von Humboldt*, (2) *Professor de Vriese*, (3) *Alexandre Von Siebold*, and (4) *Souvenir*; they are all perfectly hardy; but require to be well-established and strong plants before they produce their beautiful flowers in any abundance. Plate 10 represents a fine new seedling variety of the Pampas Grass, raised by the well-known French nurseryman, M. Bertier-Rendatler, and named by him *Glycerium argenteum carminum Rendatleri*, and said to be extremely hardy and of an exceptionally tall and vigorous habit, producing freely large heads of deep rose-coloured inflorescence which stand the wind well, and when cut and kept for winter decoration gradually change to a clear violet shade. Plate 11 represents a new and ornamental-foliaged Thorn with leaves resembling those of one of the greenhouse Ferns which originated from seed in Eastern Prussia, and is now being distributed by Mr. Van Houtte under the name of *Cratægus oxyacantha filicifolia*. It is quite hardy. Plates 12 and 13 represent a couple of blooms of the dull leaden-bluish-flowered *Amaryllis*, introduced some time since from the Brazils under the name of *Imperatrice du Brazil*; it requires stove heat, and is extremely difficult to get to flower in this country; and when the flower-head is produced it is more interesting as a rarity or curiosity than for any beauty it can be said to possess. Plates 14 and 15 represent a hardy variegated Araliaceous plant of great beauty, figured under the name of *Aralia pentaphylla* fol. var., but which seems to us most closely to resemble, if it is not identical with, a plant distributed some few years ago by our leading London nurserymen under the name of *Acanthopanax variegata*. Plates 16 and 17 represent the fine gold-margined form of the *Liriodendron tulipifera*, or saddle-leaved Tulip tree, with its curious and ornamental green and orange Tulip-like blossoms, which the tree does not produce in this country till it attains a great age, but which, in the Pyrenees and countries where it is subjected to greater extremes of heat and cold, are freely produced by young sapling specimens. The variegation of this variety is said to be much more evenly distributed, and far more constant than that of the gold-blotched variety already in cultivation, each leaf being evenly margined with bright gold. It originated in France, and the entire stock has been acquired by Mr. Van Houtte, who is now distributing young grafted plants. Plates 18 and 19 represent the fine cool greenhouse climber *Tacsonia insignis*, sent to Messrs. Backhouse, of York, from Peru, by Mr. Yarborough Greame, and figured in last year's volume of the *Botanical Magazine*, by Dr. Hooker, tab. 6,069, of which plate this is an admirable reproduction.

With the exception of the four double plates of Pears before alluded to, this completes our notice of this instalment of this interesting work. We suppose that some time will elapse before another number reaches us.

W. E. G.

ROBINIAS.

AMONG plants introduced from the New World, the Robinia, or False Acacia, stands in the front rank. It accommodates itself to the most varied conditions of soil and position, grows fast, particularly when young, and rapidly reaches full development, when its stateliness and beauty make it one of the most valuable of trees either for the ornamentation of streets and avenues, or for parks. Its pretty greenish-yellow marbled wood is, sometimes, employed in the manufacture of ornamental furniture both in this country and on the Continent, and in America it is largely used for posts and rails, for which it is found to be well suited. The tree, of which the accompanying illustration is a representation, is one of the oldest in Europe. It was raised from seeds received from North America, by Professor Robin, and was planted in the Jardin des Plantes, at Paris, by M. Vespasian Robin, in 1636. About this time, too, seeds of this Locust tree were received in England from Virginia, and soon afterwards it spread, first from France, and then from England, over all other parts of Europe. The subject here figured would, doubtless, have died long ago, had not special care been bestowed on it, in the way of clearing off such surrounding trees as at all interfered with it. It, therefore, now stands on a piece of fine lawn, and having more air, the few living branches which it possesses will, doubtless, still last a long time; but, as will be seen by the illustration, it has suffered much from the wear and tear of time. It is difficult to imagine what kind of form this tree had when in full vigour; but, in all probability, it was less symmetrical than that of seedlings raised from it, and which differ one from another greatly in habit, while among native seedlings little variety presents itself. It is, indeed, in all probability, from the old tree in the Jardin des Plantes that most of the numerous varieties now in cultivation have proceeded, and of which the following are the principal:—1. The Unarmed Robinia, a bush as common as the type, and distinguished (as its name indicates) by unarmed or spineless boughs. This variety has been named *Robinia spectabilis*. *Robinia Utterharti*, a common enough plant in gardens, obtained by M. Utterhart, in 1843, from seed of the ordinary Robinia, is undoubtedly synonymous with *R. spectabilis*. Utterhart's Robinia bore fruit abundantly, but the produce reverted to the old type. The Unarmed Robinia forms elegant bushes which, when planted in the shape of single specimens on Grass plots or on undulated ground, have a fine appearance. 2. *Robinia crispata*.—This forms a large tree, nearly all the leaflets of which (especially those of matured branches) are more or less curled or tortuous. The particular tree possessing this form in the Jardin des Plantes differs from the other kinds merely in having the superior leaflets of this character, three or four pairs, remaining entire. 3. *Robinia umbraculifera*.—This is Damont's unarmed variety, commonly called the Parasol Acacia. It is a tree of average size, close and bushy, so much so, indeed, as to form an almost impenetrable shade, a quality which renders it valuable for avenues. 4. *Robinia tortuosa*, so called on account of its twisted branching form. Like the last, it is a tree of average size, compact, and bushy. 5. *Robinia pyramidalis* (alias *stricta* or

fastigiata).—This forms a large tree, and was introduced by M. Leroy, of Angers. It has an upright habit of growth, something like that of the Italian Poplar, with which it might be easily confounded, especially in winter. The specimen in the Jardin des Plantes, is beyond doubt one of the most remarkable of trees, both as regards form and height. It was planted in 1843, by M. Pepin, and flowered and fruited for the first time in 1853. The seeds, numbering twenty-three, were sown in 1854; seventeen of them grew, and the produce was for the most part like the type. In 1859, the original tree of this kind measured 17 metres in circumference, its present height being more than 20 metres. 6. *Robinia Decaisneana*.—This is a very hardy variety, equal in development to the ordinary Robinia. It is a form obtained comparatively recently by M. Villevel, nurseryman, Manosque, Lower Alps, where it first flowered in 1862. The merit of this tree, however, lies less in

its habit of growth than in the abundance in which its bright rose-coloured flowers are produced, a colour rare among Robinias. 7. *Robinia monophylla*.—This was raised about the year 1855, by M. Deniaux, a nurseryman of Maine-et-Loire, and it flowered in 1864. It is a very variable kind.

These are a few of the best of the Robinias now in cultivation; but a few others might still be added, such as *Robinia patula*, a form of *umbraculifera*, but with wider spread branches; *R. microphylla*, *R. sophorifolia*, *R. macrophylla*, and *R. edwardsiaefolia*. *R. dissecta*, a kind whose leaflets are, we may say, reduced to their mid-rib; *R. bullata* with swollen leaflets; the common Robinia with leaves streaked with white, and another of a yellowish tint; the Marbled Robinia (*R. cornigera*), a sort armed with strong prickles; *R. monstrosa*, with branches more or less deformed or streaked; *R. pseud-acacia*, with flowers whitish-yellow; and, lastly, *R. latisiliqua*, known by the singularity of its form.—*Revue Horticole*.

One of the oldest Acacia trees in Europe.

Planting Railway Embank-

ments.—Attention has often been called to the waste land by the sides of railways, much of which might yield profitable crops; but I have another reason to adduce why such lands should not remain in their present state. Anyone who

has recently travelled in England has seen on the railway slopes numerous marks of fires, which in many cases have extended to and destroyed the hedge, and occasionally have passed, as I know to my cost, on to the adjoining property, to the considerable pecuniary loss of the company, and to the great annoyance of the landowner. No one esteems more highly than myself the advantages conferred on the public by railways; but that is no reason why such pecuniary loss and annoyance should continue, if they can be avoided, as I think they may be, by what, if it did not yield a profit, would at any rate "pay its way"—I mean the cultivation of the ground now waste between the railway and the fence, the weeds on which, when dry, are readily ignited by fire from the engines. The crops grown must vary with the soil and climate. Potatoes, Turnips, Carrots, Onions, and Cabbages would succeed on the better soils; while the poorer might be planted with herbs. The railway companies may say, "We have enough to do without becoming gardeners. True; but many would gladly pay a small rent for the land, the conditions being that the ground should be kept clean, and that the crops should be such as would be taken off while green."—M. MOGGIDGE.

THE GARDEN IN THE HOUSE.

DINNER-TABLE DECORATION.

A Simple Arrangement.

Owing to the neat and pretty appearance which a few vases of simple flowers have had on our dinner table during the last few days, I have been tempted to furnish some account of them. In the centre was a white china trumpet resting in a kind of rustic frame-work of frosted silver, and round this neat little vase were grouped four small specimen glasses. Lightly arranged in the centre piece were the following flowers, viz., small pink and white Asters, pink Pelargoniums (Christine), long sprays of blue Lobelia, a few buds of Roses (Gloire de Dijon), Mignonette, some fronds of Maiden-hair Fern, and spikes of common field Grasses. In each of the specimen glasses were single blooms of Japan Lilies, two being pink-tinted, the other two pure white; these were backed by fronds of Maiden-hair. This little group was in use four days, and on a small-sized dinner table was very effective.

Mantel-piece Decoration.

This is an important matter as regards the decoration of the drawing-room, and one to which special attention should be paid, as vases on mantel-pieces occupy very prominent positions, and, unless skilfully furnished with flowers, are better dispensed with altogether. Specimen glasses filled with Everlastings, Rose-buds, Pelargonium blooms, or similar flowers, may be seen on every chimney-piece, and they are almost invariably one-sided, *i.e.*, they face the room, all that is left for the mirror behind to reflect being the backs of the flowers or leaves, in place of as good an arrangement as that exhibited in front, which should be the case. As regards the ends of the mantel-piece, the first things to obtain are stands in which the flowers are to be arranged; these may be had of various shapes; but those best suited for this purpose are a pair of common zinc troughs, each about 10 or 12 inches long, 5 inches wide, and $3\frac{1}{2}$ inches deep, painted green on the outside and white on the inside. When about to be dressed with flowers, they should be filled with sand to within half-an-inch of the top; the sand should be then damped and covered with common Selaginella. If too much water be put on the sand, the flower-stems will not remain firm or upright. It is a good plan to have two pairs of these zinc troughs, one pair in use in the drawing-room, and the other pair with the Selaginella growing in them in the greenhouse. By this means, as soon as the flowers in the pair in use have faded, that pair may be removed to the greenhouse and the other pair introduced into the drawing-room, and arranged with fresh flowers. The greenhouse treatment soon revives the Selaginella, impaired in appearance by indoor confinement. This plan also holds good in the case of many other kinds of floral decorations in which zinc troughs or trays are employed. Round the edges of the troughs Fern-fronds should be used, and arranged so as to droop over and hide the sides as much as possible. The best kind of Fern for this purpose is the common Brake, which is sold in florist's shops in bundles; should the fronds be found too long, they can be cut as short as necessary, and the tip ends used. After the Ferns have been rightly placed, the flowers should next be arranged, and rather large and bold-looking varieties should be used, such as Roses, Lilies, Clematises, &c. These should be placed so as to stand out well one from the other, avoiding all appearance of crowding. Branches of Fuchsias look effectively mixed with such flowers as those mentioned, and plenty of foliage must also be intermixed with them. When the flowers have been arranged according to taste, the troughs should be placed on the mantel-piece, one at each end, and close to the margin of the ledge; some long sprays of trailing plants should then be inserted in the soil and allowed to droop down at each side. Sprays of *Lapageria rosea*, Clematis, Hops, Passion-flowers, Tacsonias, and similar material are admirably suited for this purpose, as are also different kinds of Ivies, which are light and graceful, and obtainable at all seasons—a great point in their favour. Those who do not care for troughs of growing Selaginella, may use, instead of them, a pair of those pretty small china pots sold at glass shops for standing on brackets and holding

cut flowers. I do not mean such as are sold for dropping pot-plants into, as the latter have always a hole at the bottom for drainage; the pots to which I refer are made on purpose to hold water in which to put flowers, and in these very effective arrangements can be made in the same way as that described for the troughs, but they can never be made to look as suitable in shape as the troughs. At nearly every season of the year we have flowers suitable for this style of decoration. In spring, we have Hyacinths, Tulips, Forget-me-nots, Snowdrops, Squills, Lily of the Valley, Lilacs, &c.; in summer, Roses, Pelargoniums, Fuchsias, Water Lilies, and Clematis; in autumn, Japanese Lilies, Roses, Lapagerias, and *Paneratium fragrans*; and in winter, those who have no glass-houses of their own, can obtain in the market Cape Heaths, Chrysanthemums, Callas, Poinsettias, and similar material. All these are adapted for this style of decoration. Specimen glasses with a few flowers and Ferns also look well on the mantel-piece, if dressed all round, but not if arranged to face only one way. A hand holding a vase, in china, is a pretty device for a few choice flowers, such as Orchids and Gloxinias; and, as a rule, richly coloured flowers are best suited for opaque vases, their deep tints being shown off to much better advantage on that kind of surface than on any other.

Screens for the Fire-place.

During the summer season, when there are no fires in the drawing-room, tastefully-decorated screens fitted into the fire-place have a charming effect. These often consist of looking glass and specimens of dried Ferns; but, as they do not come within my range, being dried, I shall pass them over, merely remarking that, though handsome, they are expensive. The best plants with which to cover screens are the common or variegated Ivies. First, a box should be procured, the width of the fire-place, to stand inside the fender; it should be made either of zinc or wood, and should be ornamented with coloured tiles—in fact, a box such as one sees on hundreds of window ledges; at each end, in the back corners, an upright iron rod should be fixed sufficiently high to meet the ornamental marble over the grate; between these rods a piece of fine wire netting should be strained, so as to form a screen on which to train the Ivy; this wire back should completely cover the iron or steel grate; over the holes in the bottom of the box some broken crocks should be placed, and over the crocks should be put a layer of Cocoa-nut fibre; then the box should be filled in with a mixture of rotten turf and some sharp gritty sand. Some nice plants of Ivy should next be procured and planted firmly in the box, and rather thickly, so as at once to cover the screen. Along the front of the box, set on the soil, may be pot plants, or the surface of the soil might be covered with Selaginella denticulata intermixed with cut blooms of large-sized flowers.

Wreaths and Garlands.

These rank among the prettiest styles of indoor floral decoration, their only drawback being that some practice is wanted to make them nice and light looking. Long pieces of wire are required for the foundations, and some bundles of Moss to keep the stems of both Ferns and flowers fresh. There are so many flowers suitable at all times of the year for this kind of decoration that I need not enumerate them, as the selection must depend on the size and description of the wreath or garland intended to be made; and, as a rule, light and airy-looking flowers are the best to select. As each flower is bound on to the foundation, after having been previously wired, it should be drawn out into the required position, and plenty of damp Moss should be bound round the stem of each to preserve its freshness. For small sprays use very little Moss; for, were it to appear, it would tend to make the wreath look heavy, but in a large garland its appearance does not matter so much; indeed, if the Moss is fresh and green, its being shown will be an advantage. Though the Moss should be damp, permit no water to remain therein beyond what does so when pressed after being washed; for, if water be allowed to drip from it, it would spoil anything the garland might happen to touch. A few sprays of *Lygodium scandens* look light and elegant twined through wreaths of any description. Heavy flowers should, as a rule, be avoided; as, though in themselves

they may be handy, they tend to give a heavy appearance to the wreath, which no amount of dressing with Ferns or other foliage will obviate. I am of opinion that if fewer Camellias were employed, and other flowers more plentifully substituted, such as Bouvardias, Stephanotis, &c., wreaths that are exhibited in the florists' windows would often have a lighter and more elegant appearance than they now sometimes present. Sprays of Ivy intertwine charmingly in this style of decoration; but young sprays of a good colour, and with small leaves, should be selected. Another creeper admirably suited for this purpose is the Japan Honeysuckle. This style of decoration is very effective where pot plants or vases of flowers cannot be employed. A. HASSARD.

PLANTS FOR WINDOWS.

THERE are hundreds of plants used for the decoration of windows and balconies during the summer months, in London and other large towns, that are nearly as short-lived as they are beautiful, lasting only a few months in perfection, and then looking withered and miserable after the first frosty night or morning in autumn. To this class belong many favourites, such as Sweet Peas, Convolvulus, Canary Creeper, Nasturtiums, and other graceful annuals, while anon the gorgeous beauty of the Virginian Creeper is comparatively short-lived, and vanishes at the approach of winter, leaving a few wretched-looking thong-like twigs, from which the cold wintry rains drip into the area or pavement below. There are comparatively few plants suitable either for window or balcony-culture during our sharpest winters, and these, few as they be, are but too seldom seen, although their presence during the dull winter months, and the first few sunny days of spring would do much towards dispelling the dreary monotony of our muddy streets, at a time when a glimpse of fresh green leaves, or the bright tints of a few flowers, is even more refreshing than during the hot summer weather, when the greenery of the deciduous trees in our parks and squares does much to attract the eye from the dusty and heated streets. We shall confine our remarks here to such plants as will thrive in an ordinary sitting-room window, premising, as a matter of course, that actual frost is excluded. For the purpose here indicated, some of the early-flowering bulbs are especially valuable, but as these, as a rule, are not very ornamental when growing, we must look elsewhere for fresh and gracefully-habited plants, amongst which they will show when in flower to excellent advantage. One of the finest of all foliage plants for windows, is *Acacia lophantha*, which bears dense, finely-cut foliage, as fresh and graceful as that of even the most delicate Fern. Pots of the slender, drooping, Grass-like *Isolepis (gracilis) pygmaea*, are always fresh and green; and as a substitute for the common fresh Moss-like *Selaginella Kraussiana*, we have the different varieties of the common Stonecrop (*Sedum acre*), which possesses a dense fresh-looking appearance all through the winter and spring. *Acacia armata* should be included by all means, for if a little less elegant in habit than *A. lophantha*, to which we have just alluded, it possesses the advantage of flowering freely early in the spring. Last January and February I had a couple of bushy little plants, scarcely more than a foot in height, and these were studded with hundreds of soft yellow globular flower-heads, which contrast admirably with the dark glossy green leaves. Another distinct and effective winter-flowering plant is the golden Pea-flowered *Coronilla glauca*, which does capitally in a sunny window, forming a glowing object of beauty in February or March, while, in the same position, *Cytisus racemosus* is quite equal, if not superior, and its rich yellow flowers are deliciously fragrant. The small-flowered or Pompon varieties of *Chrysanthemums*, must on no account be overlooked, as they are readily propagated from spring-struck cuttings, and form handsome little specimens, if pinched once or twice during the summer, so as to make them bushy. They grow freely if potted in richly-manured compost, and set on a cool border or walk to make their growth, and they need not be removed indoors until the flower-buds make their appearance, and the cold rains and frosty nights of autumn render protection advisable. The plants already enumerated would be

amply sufficient to render the windows of a town or suburban residence gay and attractive, and these are only a few of those well adapted for our purpose. Even if winter-flowering plants in pots, such as Hyacinths, Narcissi, Crocuses, Tulips, Cyclamens, forced Roses, Lily of the Valley, and Dentzias, are purchased now and then from the market, a few fresh foliage plants of permanent interest should be grown. One of the best of window plants is the broad shiny leathery-leaved India-rubber (*Ficus elastica*) and *Aralia Sieboldii* is even more attractive, having finely lobed foliage, which continues fresh and green throughout the winter. The graceful *Cyperus alternifolius*, and some of the hardier Ferns, such as *Polypodium aureum*, *Cyrtidium falcatum*, or the elegant little *Asplenium flabellifolium*, grow remarkably well in some windows year after year. For variety we have many distinct and striking forms of succulent plants, of which the smaller Agaves and Aloes may be mentioned as excellent examples. The pretty little white-flowered *Crassula lactea* blooms very freely about December and January in a sunny window, and it requires but a modicum of attention with regard to moisture. *C. quadrifida* is another member of the same group even more striking in appearance than that just named; and a few plants of such things as *Roechia falcata*, *Echeveria gibbiflora* var. *metallica*, *Gasteria verrucosa*, or some of the elegant silvery-spined *Mammillarias*, deserve a place in a dry sunny window, where they give but little trouble, and are of permanent interest, even if no flowers are produced. In order to render our window-garden arrangements pleasing to all tastes, we should endeavour to secure as much variety in habit, form, and colour as possible, and a little art displayed in arranging the plants in the window, so that they may look well from the interior as well as from the exterior, is desirable. This is a point too often neglected, and few things make a room look more dismal and uncomfortable than huddling a number of one-sided plants together, so as to make an exhibition for observers outside, while the apartment itself is robbed of its due share of air and light. Plants that draw towards the light should be turned now and then, so as to prevent their becoming one-sided and spindling in habit. A few distinct plants judiciously grouped and duly attended to, as regards occasional watering and sponging, will give more satisfaction, and look far better, than when an attempt is made to grow too large a collection without sufficient skill or means. F. W. B.

ARRANGEMENT OF FRUIT FOR DESSERT.

THIS subject has so recently been discoursed upon by your talented and tasteful correspondent in the matter of table-decoration (see p. 102), that it might seem superfluous to touch upon it again at present. But fruit is, just now, very plentiful, and there are some points in Miss Hassard's remarks to which I cannot subscribe; I, therefore, wish that your readers should have an early opportunity of comparing her views and mine on the very few matters wherein we differ. Fruit-arrangement should be treated under the two headings of arrangement on the table, and arrangement in the dishes. And, first, as to the

Arrangement on the Table,

if I could only hope that people would follow my advice, it would save my writing more than the notorious monosyllable, which contained *Punch's* advice to persons about to marry—"don't." I am adverse to fruit being put on the dinner-table at all, believing that the better plan is to hand it round, as dishes of all other kinds of eatables are served. But, if flowers are scarce, and there is nothing suitable which is available for the decoration of a dining-table excepting fruit, then, and then only, would I excuse the presence of fruit on the table, and even then there are certain fruits which I would not allow in the room (much less on the table), until the time came for offering them to the diners—to wit, Strawberries, Pines, Melons, and all other odoriferous fruits. No doubt there are many besides myself whose nasal organs have been annoyed at dinner by the smell of Hyacinths, Tuberoses, Narcissus, and other flowers. It should, therefore, be the rule to exclude from a dining-room all odours which may cause annoyance, or

prevent any guest from the full enjoyment of the meal to which he has been invited. But I go much farther, and assert that, not only should you avoid everything likely to cause discomfort, but you should endeavour in all your arrangements to give the greatest possible pleasure to the eye as well as to the palate. Now it is quite impossible that fruit which has been exposed for a couple of hours to the heat of lamps or gas, to the steam of soups, joints, and made dishes, and to the breath of diners and attendants, can be so pleasant and enjoyable as fruit brought in from a cool room and served at once; besides which there is the possibility, in the country, of its having been gathered since you began your soup, and of being, therefore, really fresh. It is a common saying, that "appearances should be kept up;" and I know of nothing to which it is more truly applicable than to fruit, which, to be tempting, should be made to look fresh, even if it be not so.

Arrangement in the Dish.

Strawberries, Raspberries, and Cherries, should never be arranged with the stalks turned inwards. The most enjoyable way of eating all kinds of fruit, is to pluck it and eat it on the spot. Apart from its freshness when thus partaken of, there is the great pleasure of knowing that no other fingers have touched it. When it cannot be eaten under these conditions, it should be borne in mind, that the fruit should always be made to look as fresh as possible, by dishing it up as late as possible, with the freshest of foliage, and it should seem as if it had not been fingered—at least the eatable part of it—by anyone. People may laugh at the extent to which fancy will carry some folks; but I have yet to learn that any harmless fancy is to be sneered at, or disregarded, because it does not happen to be everybody's fancy. With many people the eye and the nose are quite as important media of conveying pleasure at a dinner, as the mouth; and by them the greatest enjoyment is found at those entertainments where there is enough, both in variety and in quantity, to excite and interest the organs of sight, smell, and taste, but not enough to fatigue any of these senses. Cherries, Raspberries, and Strawberries should be laid as they are gathered, in the dishes in which they are to be served, and should never be touched again until they are eaten. Where this is not practicable, they should be removed from the basket in which they have been gathered to the dessert dish, one by one, the stalk only being handled; on no account is the fruit to be touched. I do not mean to say that I admire Cherry-stalks, or consider them ornamental, yet I would much rather put up with the appearance of the stalks, than partake of a dish of fingered Cherries. But with Strawberries the case is different; they have a persistent green calyx which, when seen as the fruits lie on their side, has a pretty effect, and sets off the berries to advantage. Miss Hassard has a great horror of Oranges, because they do not associate well with other fruits. No doubt their intense colour is very "killing;" and, if they are used as a side dish, there is nothing that will balance the opposite side of the table, except another dish of the same, and then "the remedy is worse than the complaint." My objection to Oranges has reference to the nose more than the eye. I can always manage to tone their colour down with foliage, or to give them a central place on the table where they do not clash with other fruits; but, unless they have been very carefully handled, their odour is very objectionable. There is a wide field open for the exercise of taste in the choice of foliage for dressing dishes of fruit, and I trust that Miss Hassard will favour your readers with further remarks on that subject. W. T. P.

Lasting Properties of Maiden-hair Fern when mixed with Flowers.—Do fronds of Maiden-hair Fern remain fresher when placed in a vase by themselves than when arranged with other flowers?—A. B. C. [This is a question which I have tested, and the following is the result:—Having selected six well-matured fronds of *Adiantum emarginatum*, I severed them from the plant with a sharp knife, and placed them in two large-sized specimen glasses, three fronds in each glass; but into one I also put three sprays of *Magnolia*. At the end of twenty-four hours the six fronds were as fresh as when first placed in the water; after forty-eight hours had elapsed, one frond in the glass along with the flowers looked a little shrivelled; at the end of seventy-nine hours, five of the fronds were as fresh as ever, the one which shrivelled at first being quite dead, but the other two remained perfectly fresh. This frond, I imagined, must have been younger than the rest, or injured in some way, as had the *Magnolia* harmed it, the other two would also have been injured. In this case, therefore, mixing flowers with Fern-fronds did no harm.—A. HASSARD.]

GARDENING AT HOXTON IN OLDEN TIMES.

HOXTON was a favoured home of some of the most noted gardeners in the seventeenth and eighteenth centuries. One of the earliest of these was Goult, who flourished in the reign of Charles II., and whose name has come down to us in an anagrammatic form attached to the Nectarine he successfully raised, viz., the Elruge. George Ricketts, Pearson, and William Darby are all three mentioned in Gibson's curious account of gardens near London, in December, 1691. Ricketts cultivated more than 190 kinds of Tulips, and he possessed the richest and most complete collection of flower-bearing trees and shrubs in the kingdom; Pearson had the best assortment of Anemones about London, and sold "them only to gentlemen;" and Darby was known as one of the first in England to cultivate exotic plants. He was succeeded by John Cowell, in whose garden flourished the *Cereus* and the Glastonbury Thorn. A great American Aloe was bought by Darby when it was twenty years old, and it remained in his garden for forty years, after which it came into Cowell's possession. When it was seventy-two years old it began to open its crown for flowering, and in June, 1729, it flowered magnificently. Large numbers of visitors were drawn to the gardens to see this curiosity. Another noted Hoxton gardener was Benedict Whitmell; but the most distinguished of the fraternity was Thomas Fairchild, who, by the judicious bequest of the small sum of £25, has succeeded in preventing his name from ever being forgotten. Fairchild united a love of science with the practice of his art, and contributed a paper on the motion of sap in plants to the Royal Society, which was printed in the "Philosophical Transactions." His grounds were afterwards known as Selby's gardens, and extended from the west end of Ivy Lane to the New North Road. Here he cultivated a Vineyard as late as 1722, which is said to have been one of the last in England. Fairchild by his will, dated Feb. 21st, 1728, "gave and bequeathed to the trustees of the charity children of Hoxton, and their successors, and the churchwardens of the parish of St. Leonard, Shoreditch, and their successors, the sum of £25, to be by them placed out at interest for the payment of 20s. annually, for ever, for the preaching of a sermon in the said church of St. Leonard, Shoreditch, by the lecturer of the said parish, or such other person as the said trustees and churchwardens and their successors should think proper, in the afternoon of the Tuesday in every Whitsun week in each year, on some subject relating to natural history." Among the noted men who have delivered the lecture may be mentioned Dr. Stukeley; the Rev. William Jones, of Nayland; the Rev. Samuel Ayscough; and Dr. Wilberforce, when Bishop of Oxford. In 1750, Stukeley made a note in his journal of a visit to hear the lecture; and as the passage gives us a picture of the state of the neighbourhood of Hoxton at that date, we will quote it here:—"I went with Dr. Folkes and other fellows to Shoreditch, to hear Dr. Denne preach Fairchild's sermon on the Beautys of the Vegetable World. We were entertained by Mr. Whetman, a merchant, at his elegant house by Moorfields, a pleasant place, encompass'd with gardens, stored with all sorts of curious flowers and shrubs, where we spent the day very agreeably, enjoying all the pleasures of the country in town." Hoxton was once noted for balsamic wells, and a book was written upon them. Sir Philip Skippon, writing to Ray (December 13, 1667), refers to "the sweet-smelling earth found in Captain Massey's garden, at Hogsden," and eighteen years afterwards, Sir Hans Sloane, in a letter to Ray (November 10, 1685), gives a full account of the earth, and an analysis of the water found "near the new square at Hoekesdon." Whatever charms Hoxton may once have possessed, they are all gone now, and yet not many months ago, a London merchant purchased ground there, and built himself a house, which was finished, and fitted up with an elegant conservatory.—*Builder*.

Remarkable Artesian Well.—One of the most remarkable artesian wells of our own time is that of Grenelle, in the Paris basin. It was undertaken in 1831, up to which time no successful artesian sinking had reached a greater depth than about 1,000 feet. It was calculated that the water-bearing stratum sought would be reached at a depth of 1,500 feet; but that was not deep enough. The boring continued, with intervals, until 1841, when, on the 26th February, the boring-rod was observed to descend suddenly several yards. In a few hours the water reached the surface, eventually rushing up with immense violence, mixed with sand and mud. But the sand and mud soon ceased, leaving a magnificent flow of pure water, which has continued ever since. A high tower is erected, and the water rises through pipes with sustained force and volume to the reservoir at the top, at the rate of fully half a million gallons per day.

It is probable, says the *Hornet*, that the much wanted new City vegetable and fruit market will be erected on the site now occupied by the Bank of England.

THE FLOWER GARDEN.

STAPHYLEA COLCHICA.

THIS species of *Staphylea* was introduced into France from the north of Europe, by M. Masson, about fifteen years ago, and how such a valuable early-flowering shrub should be so seldom met with in collections, it is difficult to understand. Its flowers, which are white, are borne in clusters, sufficiently numerous to be effective. It should have a warm light soil, and, if anything, rather dry than moist. It is increased by means of cuttings, and probably it would also succeed grafted on *Staphylea pinnata*, a stock which might be the means of dwarfing it sufficiently to make it a good market plant. About Paris it sometimes bears fruit, from which young plants are raised, and treated in all respects like those of some of the more common species.

WINTERING SUCCULENT PLANTS.

AMONG the plants that now decorate our flower gardens none are better worth keeping over the winter, or more worthy of special care during that season, than succulent plants, of which the desire to possess collections is everywhere on the increase. They will never supplant flowering plants; but, apart from their being used here and there in conjunction with them, in many places they are arranged in what may be called small "succulent" gardens, a mode of treatment for which they are eminently adapted, and under which their appearance is much more satisfactory than that of most sub-tropical plants, which in northern latitudes do not succeed. All succulent plants may be preserved through the winter successfully, provided a little attention is paid to properly storing them at first. The tender varieties of *Echeverias*, *Semprevivums*, *Gasterias*, *Haworthias*, &c., should all be lifted before they are in anyway injured by frost; this is a matter of much importance, inasmuch as the large fleshy leaves, especially of the *Echeverias*, if subjected in the least to frost, soon become soft and drop off, leaving only a few small leaves mounted on the tops of long stems, a condition which spoils the plant for another season. A frame, which can be warmed by means of fire-heat, is a suitable place in which to winter them, and a Vinery or greenhouse in which the atmosphere is dry, and from which frost is excluded, will be found to form an equally good hibernatory. If a frame is selected for them, put into it some light soil to the depth of 6 inches. Lift the plants carefully, and plant them in this in rows sufficiently far apart to prevent the plants touching one another, but not more, as they will not grow much during winter. As each row is laid in, a gentle watering should be given, and a layer of 1 inch of river sand should be put over the surface of the soil; this keeps the bases of the stems dry, and also assists in maintaining a drier atmosphere throughout the winter. They can, of course, be potted and wintered in the same place; but, when planted out, a greater number of plants can be got into the same space, and the labour attending potting is saved. After the first watering, little more is needed until well into spring,

and they may be allowed to remain in the frame until they are required for planting out again, when they will be found to lift with large balls and plenty of fine roots. The temperature in hard frosty weather may be allowed to drop to about the freezing point, but never below it. Abundance of air should be given on all favourable opportunities, and the atmosphere should at all times be kept as dry as possible to prevent damping. If water is given or needed at any time, it should be applied without letting any of it fall into the centres of the plants; for, when that happens, the heart soon begins to rot, and the plant is destroyed.

When succulents are kept in greenhouses or in Vineries, I prefer placing them in boxes to any other way. Cutting-boxes—from 4 to 6 inches deep, according to the size of the plants which are to occupy them, should be filled in much the

same way as has been directed in the case of frames, and the plants should be set closely together in them. In this way great quantities of the smaller kinds may be got into comparatively little room, and the boxes may be conveniently set on the top of the hot-water pipes, on the back-wall shelf, or in any vacant corner in which they will be undisturbed. Any leaves that show signs of damping off should be pulled clean off at the base—an operation easily done without injuring the stem. These remarks apply to such succulents as require protection from cold and damp throughout the winter. Dwarf hardy kinds of the House-leek type are capable of enduring, with impunity, all kinds of fluctuations of temperature. Many of them, indeed, acquire their brightest hues of foliage during cold bleak weather early in spring; therefore, unless some alteration as regards arrangement is desired, they may be left all winter undisturbed in their summer positions, where they form useful additions to winter and spring flower gardens. When thus treated, the off-sets, which sprout out around the old plants in summer, should be removed and planted, or "dibbled" closely in in rows in any reserve piece of ground, the soil of which is light and sandy. When taken off they will be found to have but little root, but plenty of young rootlets are soon emitted, and nice plants for bedding the following spring are thus secured. In cases in which the ground has to be cleared, dense-growing kinds may be lifted in patches and placed in any empty bed or corner of a border where they can have a little soil put round their roots, while such as have grown into tangled masses may either be divided at once and temporally planted singly, or left untouched until March, and then separated and planted where they are to remain. Succulents, indeed, are so tenacious of life that they may be divided either in autumn or in spring, with equally satisfactory results.

J. MUIR.

Clovenfords.

Blooms of Sweet Peas for Market.—Sweet Peas are chiefly grown in market gardens to supply an early crop of blooms, which, however, they also furnish throughout the summer and autumn; but the early ones are the most valuable, and the more they are cut, the more do the plants produce. The earliest sowings generally yield a

Staphylea colchica.

heavy crop, provided they are made in moderately moist and rich soil. The summer and autumn crops, owing to bright weather and drought, are often short-lived. Mr. Pocock, Mortlake Road, Kew, sows his earliest Sweet Peas along the sides of walks that run through his grounds, in October or November, and when they come up a little earth is drawn to them. They are staked early in spring, and if the weather be favourable, they begin to bloom in April, and continue in good condition until July. All expanded flowers are cut for market three times a-week. They are tied into bundles in large handfuls, packed in baskets like Wallflowers, and sold in this way in the wholesale market. These market bunches are converted by the retail dealers into several small ones, which they sell for a penny or two-pence a-piece; but they retain all the best flowers for bouquet making. A portion of the produce of either the first or second sowing is left untouched, after having been picked from for about three or four weeks, for next year's seed. When the latter is ripe, the plants are cut over or pulled up, tied into bundles, dried in the sun, and kept in a loft until thrashed out.—P.

Novel Way of Treating Hollyhocks.—I am a great admirer of Hollyhocks, but I dislike the coarse and unsightly appearance which they assume in a short time after the first flowers have faded, or been reduced to a pulp by rain or strong sunshine, and also the inferiority of the extreme terminal flowers of the spike. To obviate this last defect I have been in the habit of cutting out the top while the lower blooms were in perfection. This year during my absence from the middle to the end of June, my man thought he was doing good service by removing the tops before the flowers appeared. The result has been to spoil the main spike, which grew up stunted and closely packed; but to make up for the disappointment, from every axil on the main stalk there has sprang out a number of shoots, forming elegant and graceful branches, to the number of more than twenty on some of the plants. These are now covered with perfect flowers, nicely spaced and distinct, alternating with very small leaves, and they look as if they would continue in perfection for another month. I do not know with what to compare their appearance; I have seen nothing like them. As these shoots grow uniformly round the stem, the general outline is that of a trained pyramidal tree with about 100 flowers expanded at once, and you may conceive what a fine effect the various beautiful shades of colour must produce. If any of your readers are inclined to try the experiment, I would recommend having only one stalk left on the stool which can be more easily staked and secured than a greater number, and will form a more elegant object than a number crowded together as usual. I may add that I have just been measuring one of them; it is 7 feet high, and 4 feet across at the lower part, tapering to the top. The side shoots do not exceed half an inch in diameter.—J. W.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

New White Phlox.—We have sent you a piece of Phlox Miss Robertson, but not in good character, being drenched with rain, and only from spring-struck cuttings. We may inform you that we have grown it as large again.—J. COCKER & SONS, *Aberdeen*. [The flower-spikes received were very large, pure white, and deliciously fragrant.]

Plants for a Steep Rock-work Facing North.—Kindly inform me what plants will do best on a bare steep rock-work with a north aspect.—G. W. B. [*Alyssum saxatile*, *Arabis albidula*, *Artemisia frigida*, *Astragalus monspeliensis*, various *Aubrietias*, *Campanula crepata* and its varieties, *C. fragilis*, *C. eardleyana*, and *C. turbinata*; different kinds of *Cerastium*, *Coronilla varia*, the Maiden Pink, *Iberis sempervirens*, *Lysimachia Nummularia*, *Phlox reptans* and *subulata*, *Saponaria ocyroides*, various *Saxifrages* and *Sedums*, *Thymus lanuginosus*, *Vicia Cracca*, and *Vinca major* and *minor* and their varieties, *Genista prostrata*, *Daphne Cneorum*, some of the dwarf *Cotoneasters*, *Rubus arcticus*, and *Polygonum complexum*.]

Silver-leaved Edging Plants.—What is the best silver-leaved edging plant? I want it for beds on Grass, and, if possible, it should be hardy, and a good match in general size to the *Pyrethrum* or Golden Feather. I should also like to know how it is best propagated, and at what time of year.—R. J. K. [The dwarf silver-leaved *Enonymus naphens* might possibly suit you. It is propagated by means of cuttings put in in spring. *Cerastium Biebersteinii* is also hardy and grows freely, as does also *Stachys lanata* or "Lamb's Ear;" both plants are readily propagated in autumn or spring by means of cuttings or division. Of these, the *Cerastium* will, perhaps, suit you best, as it succeeds well in any soil and climate.]

Maréchal Niel on its own Roots.—Will some Rose authority advise me in the following case? Last spring, a strong plant of Maréchal Niel on its own roots was planted in an old Vine border, and brought through the wall into the greenhouse. It has made a great growth, but shows hardly any flower-buds. Now, is there any hope that it will flower freely on its own roots? I rather fancy not from what I read in your paper two or three weeks ago, but I should be very glad of advice.—*SALMONICERS*. [There is no reason why your Rose Maréchal Niel, on its own roots, should not flower freely next year. Much, however, depends on the manner in which it is pruned. Prune in January, leave the long vigorous shoots their entire length, or, if they are not ripened to their ends, cut off only so much as is not ripened; then, cut off the small and moderate shoots, leaving from four to six eyes on every shoot. If there is a greater number of shoots than you require to fill the space at your disposal, cut out where indifferently ripened or crowded.—*Wm. PEARCE*.]

A NOBLE GIFT OF A GARDEN.

So much has recently been said respecting the gift of Leicester Square, &c., that the following account of a noble botanic and public garden, presented to the city of St. Louis by one of its citizens, may not be without interest:—Of the various enterprises of the West identified with ornamental gardening, the most prominent which we have seen in our travels is that of Shaw's Gardens, St. Louis. As a botanical garden it is, perhaps, the very best in the West, as pains have been taken to gather together a large number of the best specimens of each class of plants. But its celebrity has come mainly from its popularity as a pleasure resort for the citizens of St. Louis. It bears the same relative position in St. Louis among pleasure lovers, as the Central Park in New York city, or Woodward's Gardens in San Francisco. Originally known as the Missouri Botanical Garden, it was founded in 1858, by Mr. Henry Shaw, a wealthy citizen of the city. Possessing a love for rural ornament and gardening, as well as being the owner of an immense landed property on the outskirts of the city, measured by the square mile or more, he began the formation of the garden, both for personal amusement and yet with benevolent purpose—to afford a good example to the encouragement of rural taste. It has grown in his hands from small beginnings until at last it fills a space of 110 acres. The city has grown out to it; its finest avenue now skirts his property; and, like many other places of like beauty, it has passed from its uses as a private place to its form as a favoured resort for the public, and some time since was presented by him to the city, and now is the most acceptable place of enjoyment in the vicinity. There are various nurseries connected with the gardens, in one of which there are 20,000 plants growing, which will be set out in adjacent parks. There are often as many as thirty-five gardeners employed in the grounds, earning on an average two dollars per day. Connected with these grounds is the botanic hall, a red brick building with high steps. It is 35 feet wide, with a depth of 70 feet. Upon the floor is a beautifully tessellated pavement, and over-head a frescoed ceiling of artistic colours. Magnolias, Palm trees, Oleanders, Morning Glories, Pines and their cones, Lilies, Apples, Cotton flowers, Tobacco plants, with different fruits, flowers, and plants of the tropics and temperate zones, are woven into graceful garlands in the ceiling surrounding the skylight. It is hardly possible to tell all the treasures kept within these walls. Specimens of natural history, seeds of all kinds of vegetables and grain, bottled and arranged together, Pine cones of all sizes, Papyrus, Feather flower, silk from worms fed on Lettuce and Mulberry leaves, the Lettuce showing much the best in colour, tea from Paraguay, the Sponge plant, fibre of the Palm tree, Angora wool, Egyptian Wheat, Cotton from Greece, Sea Island cotton, and an immense collection of birds and stuffed animals. It is a round of great practical interest, and instructive to every visitor. Close at hand is the residence of Mr. Shaw, wherein all are welcome, and here is kept the record of all visitors, many of them famous. Just beyond is the now justly popular Tower Grove Park of 70 acres, a gift from Mr. Shaw to the city, already beautifully planted and kept. On our return from his house we pass the splendid octagon mausoleum, designed for his final resting place, built of hewn stone, with eight arches, overhung with trees which cast a deep shade. We trust it will be long ere it opens to receive him. Close by is another tombstone, raised as a tribute of respect to a gardener, osteemed for his devotion to horticulture, bearing this inscription:

TO THE MEMORY OF

THOMAS NUTTALL,

Born in England, 1786; died Sept. 1, 1869.

Honour to him, the zealous and successful naturalist, the father of Western American botany, the worthy compeer of Barton, Michaux, Hooker, Torrey, and Gray.

Within the past year Mr. Shaw has rebuilt his conservatory on a much larger scale. It is now 210 feet in length, almost as long as the great Palm-house at Kew. This garden has cost Mr. Shaw over twenty years' work, and 20,000 dollars a year. It has been wisely expended, for to the citizens of the city and state the beautiful sight has always been open "without money and without price." And now it has been devised to the city for ever. In addition to this handsome bequest of gardens and parks, covering an area of 200 acres, worth at least 200,000 dollars, Mr. Shaw has made sufficient provision in his will to keep and sustain them through all coming generations.—*Horticulturist*.

The Future Necropolis of Paris.—This is to be at Méry. The Municipal Council have resolved that a prize be offered, a few months hence, for the best system of incineration, and that the Assembly be petitioned to pass a Bill allowing cremation to be facultative in the city of Paris. Méry-sur-Oise is thirty-four kilo-mètres north of Paris.

THE SHAKESPEAREAN GARDEN.

The Flower-de-luce.—The Flower-de-luce, several times mentioned by Shakespeare as the heraldic emblem of France,* is generally understood to be that beautiful yellow-flowered species of Iris often called the Water-flag. When adopted as the national badge is not known. Some refer it to the time of Clovis, others to the period of Louis VII., soon after which the shield of France was incorporated with that of England, and the golden Lilies, on their blue ground, stood in company with the three golden lions for centuries, disappearing only in 1801. Perdita's Flower-de-luce † was probably the great purple German Iris (I. Germanica), though several of the species of the genus had been cultivated in gardens from a very early period.

The Daffodil.—This is another of Perdita's flowers, being mentioned incidentally, in the same scene as the Flower-de-luce; with a second allusion in the verses sung a little previously by Autolycus. There is no reason to suppose that anything was intended by Shakespeare beyond the common yellow Daffodil of our English meadows, but it is to be observed that the florists of the period give the name to the whole genus *Narcissus*, the Daffodil itself being distinguished as the pseudo-*Narcissus*. No mention appears to be made of this plant by any earlier author.

The Violet.—Shakespeare's Violet was unquestionably the common *Viola odorata*. The name is applied however, by Gerard, to the Snowdrop and the Snowflake. He is particularly happy in his indication of the very special habitat of this sweet flower, as in the well known lines,

O, it came o'er my ear like the sweet south,
That breathes upon a bank of Violets,
Stealing, and giving odour. ‡

How exact again the indication of his personal acquaintance with it in the epithets of "nodding" and blue-veined. Altogether Shakespeare mentions this flower upon fourteen separate occasions.

The Carnation.—What Shakespeare has to say about the Carnation comes again from the lips of Perdita, who specifies them as "the fairest flowers o' the season." A very considerable number of varieties were cherished in gardens, the plant having been a favourite from time immemorial, though not mentioned in the classics.

The Columbine.—Nothing can be more simple than the allusions to this pretty and lady-like flower, mention of which is made twice.§ Though indigenous, it would seem to have been grown in gardens, since Ophelia has it in her hands along with Rue and Rosemary.

The Cowslip.—How often must the poet's eyes have rested in May mornings upon this darling of the meadows, the name occurring in no fewer than seven different passages, and the frequency of the mention, of course, being a gauge of the love felt for it. How exquisite, too, the epithets. At one time it is "tall," || this one, referring not to stature, but to the remarkably erect growth of the flower-stem, so different from that of the many little neighbours right and left, none presenting an attitude that could fairly be denoted by the same word. At another time it is "freckled," the picture here referring to what elsewhere the poet speaks of as the "drops i' the bottom," namely, the five beautiful scarlet spots, one to each lobe of the corolla, or, as in the "Tempest," the Cowslip's "bell." The Oxlip is well distinguished by the epithet of "bold," the plant being, in all respects, so much more imposing than the Cowslip. Shakespeare's plant was, no doubt, the form usually understood to be a cross between the Cowslip and the Primrose.

The Primrose.—The feature which most took Shakespeare's fancy in the Primrose appears to have been the light colour of the blossom when compared with other vernal yellows. Upon these several occasions he refers to the "pale" Primrose; while Perdita, in the scene which, of all others in Shakespeare, is the flowery one, adds that they "die unmarried." This curious expression seems to point to the early season of their perfection, flowers being fancifully supposed to be the

brides of the sunshine personified in Phœbus. Very beautiful, at the same time, is the description of a pleasant way to a place as the "Primrose path," a figure which occurs in Macbeth, ii. 3; and again in Hamlet, i. 3.

The Marigold.—This one was emphatically and especially the flower of the sun. Like so many of the others, it belongs to Perdita, and is charmingly described as retiring to rest when the day closes, and re-appearing when the daylight returns, covered with dew.

The Marigold, that goes to bed with the sun,
And with him rises weeping.

Everyone has noticed how true this is to Nature; the rays, that are so widely expanded at high noon, drawing closely together as twilight descends, and remaining shut until the next morning. The Marigold is a native of Continental Europe, and no doubt was of very early introduction, not so much, probably, as an ornamental plant, as for the esteem in which it was held as a pot-herb. This flower is also called by Shakespeare the "Marybud."

The Daisy.—The Daisy, one would have thought, Shakespeare would likewise have adverted to as one of the sleeping flowers, not even the Marigold being more conspicuous in respect to the evening change of position of the rays. But the references to this little gem of the greensward are of the most trifling character, and only one epithet is bestowed upon it, that of "pied," which refers to the pretty tipping of the rays with pink or rose colour.

The Buttercup.—Though not spoken of by its current appellation, there can be no doubt that this is the plant intended in Love's Labour Lost:—

When Daisies pied, and Violets blue,
And Cuckoo-buds of yellow hue,
Do paint the meadows with delight.

It is impossible for so abundant a field-flower not to have fastened many a time upon Shakespeare's fancy; the associations, moreover, with the Daisy and the Violet seem to leave no room for doubt, though it is true that Violets do not ordinarily grow in meadows.

The Cuckoo-flower.—This, which is casually mentioned in King Lear, allows, perhaps, of being identified more certainly; since in the old herbals it appears always as the vernacular name of the *Lychnis Flos cuculi*. In some parts of England the name of Cuckoo-flower is given to the *Cardamine pratensis*. The same old authors give also, as an equivalent of *Flos cuculi*, the English Crow-flower; but this last, mentioned casually, like the preceding, in Hamlet, is more probably the common Buttercup, just referred to.

The Harebell.—Not a little curious is it that, while the generality of the more obvious of our wild flowers have names more or less correspondent with them in other European languages, the Harebell, in this respect, stands alone. Once only is it mentioned by Shakespeare, viz., in the exquisite comparison above quoted:—

Thou shalt not lack
The flower that's like thy face, pale Primrose; nor
The azur'd Harebell, like thy veins; no, nor
The leaf of Eglantine, whom not to slander,
Out-sweeten'd not thy breath.*

The delicate light blue of the *Campanula rotundifolia*, the plant intended by Harebell, though the latter is sometimes applied to the *Scilla non-scripta*, is precisely that of the tender veins upon a white neck or white arm.

Eglantine.—This, which is an old name for the Sweet Briar, is by Chaucer spelt Eglantère. No references are made to the plant by Shakespeare, except the above, and the familiar one in the Midsummer Night's Dream:—

Quite over-canopied with lush Woodbine,
With sweet Musk Roses, and with Eglantine.

Being indigenous to our own country, and so attractive in the odour of the foliage, Sweet Briar was doubtless one of the very first plants to be carried from the wilderness into the garden.

The Woodbine.—Over the Woodbine there is some little difficulty. In his reference to the "Woodbine coverture"

* Henry V., v. 2; 1st Henry VI., i. 1 and i. 2; 2nd Henry VI., v. 1. † Winter's Tale, iv. 3. ‡ Love's Labour Lost, v. 2; Hamlet, iv. 5. § Midsummer Night's Dream, ii. 1. || Twelfth Night, i. 1.

* Cymbeline, Act iv. sc. 2

Shakespeare intends, most clearly, the Honeysuckle; but when, in the same play, *The Midsummer Night's Dream*, he says,

So doth the Woodbine the sweet Honeysuckle
Gently entwist.

he cannot mean the same thing. Here we seem to have the great white *Convolvulus* of the hedgerows, which bears the name of Woodbine in Wm. Bulleyn, temp. Henry VIII. So, at least, it appears from his speaking of its "sweete Lillies," the identical name given by Pliny to the *Calystegia* flowers.

The Hawthorn.—The Hawthorn or May is spoken of by Shakespeare in six different places, sometimes as an accompaniment, in its fragrant white bloom, of the vernal season, sometimes as a thorny shrub.

Long Purples.—These are considered to be the flowers of the early purple or Meadow Orchis, the *Orchis mascula* of modern botany.

The Pansy.—And lastly, we have the Pansy, in the middle ages an emblem of thoughtfulness, perhaps because of the somewhat nutant position of the flower upon the peduncle. The name, which is French, exactly expresses the emblematic character. Once, Shakespeare calls it by a name long since disused, viz., "Love in Idleness."

Such, then, are the constituents of the Shakespearean garden, legitimately so called. Considering how many more ornamental flowers were cultivated, in addition to those he mentions by name, one cannot but feel what good taste he shows in the selection. Going through the pages of Gerard and Parkinson we find scores of others, more or less beautiful, described, the Tulip, for instance, the Larkspur, the Hollyhock, the Pink, and the Wallflower. British or wild flowers, in great variety, must also have been familiar to him; the scarlet Poppy for instance, the Forget-me-not, and Willow-herb. Estimating the floral wealth of our island at the time he wrote, we must not limit it, therefore, to what Shakespeare actually speaks of.

Passing on to the weeds and wild plants, which scarcely claim to be designated flowers; Shakespeare mentions Sedges, Burdocks, Reeds, Mallows, Nettles, Docks, Darnel, Brake, Briers, Brambles, Cockle, and Fumitory. Among trees, he adverts to the Ash, the Aspen, and the Birch; the Elder, the Lime, the Holly, and the Oak; the Pine also, the Bay, the Box, the Cedar, and the Cypress. We have reference likewise to Ivy, the Mistletoe, the Willow, the Osier, the Hazel, and the Yew. The fruit-bearing class is illustrated in the Apple and the Pear, the Apricot and the Cherry; while among fruits, considered independently of the trees producing them, mention is made of Mulberries, the Olive, the Pomegranate, Quinces, Dates, Figs, Grapes, Lemons, Filberts, and Medlars. Among culinary herbs and vegetables, we have Parsley, Samphire, Radishes, Turnips, Cabbage, Garlic, Leeks, Lettuces, Marjoram, Mint, Mustard, Peas, Beans, and several others. The agricultural or farm plants comprise, as would be expected, Wheat, Barley, Oats, and Rye; Vetches also, Clover, and Burnet. Pig-nuts, Ferns, Mosses, and Toadstools, also receive mention. And lastly, we have the imported vegetable productions which were employed in the Shakespearean age in the arts or in medicine, these include Cloves, Ginger, Mace, the Nutmeg, Pepper, Senna, Colocynth, &c.

Is it Possible?—Reading in a West London local paper an account of the various glories of Mr. Albert Grant's new mansion at Kensington, we came upon the following statement:—

To secure an uninterrupted view of Kensington Gardens, Mr. Grant has purchased the pretty antique lodge at the entrance to the gardens, together with the dead wall enclosing the grounds. These are being removed, and in their stead a handsome range of gilt iron railings, similar to those opposite Holland House, will be erected.

We had imagined the parks of London were not to be violated in this manner. Certain it is, in any case, that the old residence of Mr. Mann and Mr. Gibson is being demolished. It would be interesting to know if this has really been brought about through the influence of any private individual, and, if so, under what conditions.

ABIES HOOKERIANA.

(ABIES WILLIAMSONII.)

THERE are two species of Fir, lately introduced from California, that deserve more attention than they have received; one of them is the above named *Abies Hookeriana* or *Abies Williamsonii*; the other is *Abies Pattoniana*, otherwise called *Abies Hanburyana*. They are very like each other and nearly allied, although distinct, and are the type and sole representatives of a special form not very distinct from the Hemlock Spruce, of which they have the small leaves. *Abies Pattoniana* was introduced by the Edinburgh Oregon Botanical Association. It was found, in 1850, on the Mount Baker range of mountains, near Fraser River, in lat. 49° north, by their collector Jeffrey, and in 1851 they received seeds of it accompanied by the following remarks:—"It made its appearance at the point where *A. canadensis*" (this must have been *Abies albertiana* which Jeffrey had not distinguished from the common Hemlock Spruce) "disappears, that is at an elevation of about 5,000 feet above the level of the sea; from that part to the margin of perpetual snow it is found. Along the lower part of its range it is a noble-looking tree, rising to the height of 150 feet, and 13½ feet in circumference. As it ascends the mountains it gets gradually smaller, till at last it dwindles into a shrub of not more than 4 feet high." It was named by the Oregon committee after Mr. George Patton, of the Cairnies, afterwards Lord Justice Clark.

Abies Hookeriana is the representative of *A. Pattoniana*, farther to the south. It was found first by my brother, Mr. William Murray, on Scott's Mountain, in the northern part of the Sierra Nevada, and I described it in the *Edinburgh New Phil. Journal*, April, 1855, under the name *A. Hookeriana*. Two years later (1857) it was described by Dr. Newberry, under the name of *Abies Williamsonii*, in one of the botanical reports of the United States Pacific Railroad Explorations—Dr. Williamson having been the commander of the party to which Dr. Newberry was attached. They found it on the summit of the Cascade Mountains; my brother found the tree 50 feet high; one that he cut down measured 47½ feet high, and over 20 inches in diameter at the stump, and more distinguished by its gracefulness than its size. The timber was hard and tough. Dr. Newberry says:—"It forms a tree 100 feet in height, of which the form is rather spreading and irregular, but remarkably graceful." Mr. Lobb, in some remarks regarding it, published by Mr. Low, of Clapton, in a contemporary some years ago, says:—"In habit of growth and general appearance, it much resembles the Deodar, but being more thickly branched and more densely clothed with foliage, it is by far a handsomer tree." This exactly corresponds with a drawing of the tree which I received from Mr. William Murray, and which I subsequently utilised as a plate in Lawson's "*Pinetum Britannicum*." I need not occupy space in going over the specific differences between the two. It will be sufficient to give one character, which will enable them always to be readily distinguished. The leaves of *Hookeriana* are not serrated, and are silvery, or rather, mealy, both above and below, and large stomata are scattered irregularly over both sides. The leaves of *Pattoniana* are slightly serrated towards the tip, and are only silvery below; there are no stomata on the upper surface, and those on the lower are small and in long close rows. But for this character, it would be difficult to distinguish the one from the other in the young state as we see them in nurseries. There they are very generally planted near each other, and so it is easy to know that the darker coloured one is *Pattoniana*, and that with a lighter mealier hue *Hookeriana*. I had the opportunity of seeing it in its native habitat last year, and can bear my testimony to its beauty. I paid a visit to the Sierra Buttes Mine, the most prosperous gold mine at the present day in California, which lies high up in the Sierra Nevada, in Plumas county, occupying a considerable part of a sort of hog's-back ridge, standing by itself above the general level of the mountains, crowned by precipitous peaks and fanciful buttresses. Near the mine a good many fine specimens of *Abies Douglasii* and *Picea nobilis* still grow on the steep side of the mountains, although the constant and increasing demands of the mine are rapidly making it bare. A great part of the

HOOKE'S SPRUCE ON MOUNT SHASTA, CALIFORNIA.

range is, however, naturally without wood, and, at a distance, looks as if covered with a carpet of Grass. This is a deception common to all the mountains in California. It is not Grass, but a thick-grown, almost impenetrable, covering of Manzanita (*Arctostaphylos glauca*), a kind of *Arbutus*, of from 6 to 10 feet high, which grows over the whole of the country, and covers the face of the ground as thickly as a hedge, and is equally impassable. Before coming to the Sierra Buttes Mine, I had visited a neighbouring mine, named the Eureka, and had the place of the former indicated to me. I was told it was only seven miles off, as the crow flies, and it looked a uniform surface of smooth grassy slopes, which one might cross in a couple of hours. But these grassy slopes consisted of Manzanita, and we had to go sixty-five miles round to get past them. After passing through a tract of Manzanita, still ascending, trees began again to appear, consisting of the *Abies Douglasii*, a small-leaved *Nobilis*, and, at last, *Abies Hookeriana*, and it bore away the palm for elegance and beauty. It grew higher up the mountain than any of the rest, and it was to its branches that we tied our horses' bridles when further progression on horseback became impossible. It had less of the Poplar habit than the other Conifers in California. Even those which at home spread freely, seem there, whether growing singly or in forests, to be all straight and narrow in their habit; the Douglas, for example, which here flings its arms abroad so wide, is always there like a sentinel at attention. *A. Hookeriana* droops more gracefully; and the firmness and bluish glitter of its small leaves, with the young twigs and leader feathered along the stem, give it a peculiar character of its own. I saw no more beautiful tree in all California. ANDREW MURRAY.

THE KITCHEN GARDEN.

VEGETABLES FOR THE WINTER AND SPRING.

SELDOM have we experienced such a trying summer for the majority of culinary vegetables as the one now nearly over—at all events in the southern portion of the kingdom, where, in most places, the rainfall has not amounted to as many inches as the months that have elapsed since the advent of the year; and this, be it remembered, after some nine months of preceding dry weather, which, at the end of the past year, reduced the surface wells to an unprecedentedly low condition. The inestimable blessing of an abundance of good water cannot be fully realised by those who have never lived where the supply has run short. Within the last fortnight, in the neighbourhood of London, the long-looked-for rain has come, not in quantities to affect the wells to any considerable extent, and, though sufficient to set the flagging vegetable life in motion, too late to ever make the crops, upon which the principal winter and spring dependence has to be placed, anything more than half what they usually are. The late sowings of Turnips are all but failures, and can never come to anything more than tops. Winter Cabbage, Broccoli, Coleworts, and Kale, even where the land is rich and in a high state of cultivation, are very poor and small. Some there are who advise the sowing of Turnips, Kale, and similar things, even thus late; but, unless we are to have the sun fixed for a time above our horizon, it is just as well to allow the seeds to remain in the bags, for it cannot possibly be worth anything, and will only interfere with the preparation of the ground through the winter for other crops. Yet the prospect for many gardeners of being able to supply the cook with anything like the accustomed quantity of the greater portion of ordinary winter vegetables is such as will put many to their wits' end, and not a day should be lost in getting in every plant that can be obtained of Coleworts, green Kale, Savoy, and Cabbages. Those who are fortunate enough to have a quantity of July-sown Cabbage plants for next spring's supply cannot do better than put in every plant, regardless of how much they may exceed ordinary seasons, in well-prepared ground, at about 9 inches asunder each way. Of these every other row, and the alternate plants in the remaining rows, can be drawn even in a small state, and will, although not large, and inferior to full-grown Coleworts, be found much better than nothing to fall back upon. But in the increased breadth of these things planted, care should be taken not to put them where they will interfere with the trenching and preparation of the ground for another season, otherwise the usual rotation of cropping may be seriously interfered with. Even late as it is, a good deal may be done to accelerate growth by extra attention—keeping the ground stirred with the hoe through the autumn, and clear from weeds, especially if we have a protracted summer, which may reasonably be expected from the unusual

amount of heat accumulated in the earth. Not a single Cabbage stool should be removed, but as the crop is cleared off, the ground should be well soaked with manure-water. This particularly refers to such as are ready at the present time, which, if done growing, should be at once cut, so as to encourage second growth. Much more than the usual breadth of winter Spinach should be grown; this can be done by planting the thinnings out of the earliest sowings on well-prepared ground. These, if raised with a fork or the planting trowel, so as not to destroy more than unavoidable of the smaller fibres, will quickly begin to grow, and produce a crop that will be very useful before Christmas. One effect the late rains will have upon winter and spring Broccoli, will be to start them off again at a time when they have usually, in a great measure, made their growth, and are becoming every day better matured and enabled to withstand the winter. I have not the presumption to indulge in weather prognostications, but we have for the last two winters had very little frost, much below the average, and consequently may reasonably look to the coming winter as likely to be more severe, the effects of which late-growing vegetables will be in the worst condition to stand. Any ordinarily severe winter that comes, there are quantities of Broccoli that are killed through not having been in any way prepared to withstand the weather. It is well known that heeling the plants over has a beneficial effect, by checking their growth, yet this does not always get done; but in the present autumn there should be nothing left undone to preserve the little we have got. This heeling the plants over is not near so effectual as a means of preserving them from frost as absolute removal, which, in addition to this, has other advantages. The dampest parts of a garden are often selected wherein to plant the different varieties of winter Broccoli; now, such situations as these are just the places worst calculated to enable them to bear severe frost. If the plants at the end of October are taken up carefully, with all their roots, and planted on a dry piece of ground with their heads well over to the north, it is very seldom that a winter comes that will kill them. Again, some of the latest varieties can be laid in this way at the north side of a wall, which will cause them to come in three weeks later in the spring; giving so much better a chance of bridging the time over until the early Cauliflowers are ready. If the Broccoli thus removed is wintered upon a piece of ground that in its turn has been trenched previously in the autumn, it is still better enabled to withstand even the severest frosts, from the dryer condition of the land consequent upon the recent trenching. The effects of this I have repeatedly noticed, and it is nothing more than in accordance with every-day experience that where the land has been deeply stirred, so as to render the surface dryer, whatever crop is upon it suffers less from frost.

Importance of Irrigation.

Dry seasons, like the present, force upon us the consideration as to the necessity of an unstinted water supply, for large private gardens especially. Through the midland and southern parts of the kingdom I am aware that, in some cases, the kitchen garden is placed in the only situation possible; yet in many more instances there is not a thought directed to what would render it of redoubled value—that is, if a head of water was available so as to enable its being irrigated at pleasure. This would necessarily involve the garden being lower than some of the surrounding ground; but it does not follow that it should be in an objectionably low situation, and consequently in a position most likely to suffer from spring frosts—although it often happens that in the anxiety to get the kitchen garden as far as possible out of sight, a low-lying piece of ground is selected. The amount of produce it is possible to get from a limited space, where water in abundance can be had, so as to run it on in the quantities required, is only just beginning to dawn upon us, through the results of sewage and summer irrigated farms, which go clearly to prove that a piece of land, under almost any kind of crop, that is supplied with water to the full extent of its requirements, will produce something like double the weight of crop, that can be obtained in the ordinary way—to say nothing about the quality. Half the vegetables produced in this and similar seasons will bear no comparison with such as are grown under conditions of sufficient moisture, either naturally or artificially obtained. In the southern division of the kingdom, this summer, except in individually favoured spots, to produce one-half the usual vegetables has been a simple impossibility; and such as have been forthcoming, have scarcely been fit to eat. After the few first weeks Peas were flavonless, and as hard as bullets, literally roasted in the shells before they were fully grown. Broad Beans were the same. Turnips were either non-existent, or tough and unactable; Cauliflowers small and unkindly, hard when cooked, and devoid of flavour; summer Lettuce, after the first crop, bolted before half grown; Beet and Carrots about half their usual size; and so on to the end of the list. The meagre supply in the markets from those who grow for sale, and who generally manage to find the

most suitable land for the purpose, is sufficient proof of the impossibility of producing vegetables in the wanted quantities in such seasons. But it is not alone the culinary vegetable department that would be benefited by a water-supply, but fruits as well. The finest Strawberries it is possible to grow, both in size and quality, can be produced, in the driest seasons, on land that can be flooded betwixt the rows. Apples, in most places, are a third under their usual size, through drought at the roots. Pears, in almost every garden, could be seen with their leaves flagging, and the fruit correspondingly small and gritty; Plums are in a similar plight where the crop was at all heavy. On walls the different fruits have been, in many places, even in a worse condition. So far as this question concerns market-gardeners, the majority are, no doubt, unable to do anything; for, even if a head of water existed that might be brought upon a given piece of ground, the chances are ten to one that to get at it land belonging to some other individual or holding would have to be traversed, which would render the thing impossible. Not so in many gentlemen's gardens; in great numbers, from the position in which they are placed, water might be obtained in unlimited quantities, and at a cost in conveying insignificant compared with the advantages accruing. This is so patent to anyone who has had an opportunity of proving the advantages it affords, that the reason there has been so little done in this matter through the country can only be accounted for by the fact that gardeners are only too often obliged to confine their wants within very narrow limits; so much so, that the results of their labours are rendered half nugatory by a spirit as short-sighted as it is penny-wise. In the choice of a site for new gardens, especially such as are important, this water-supply should be made a matter of the first consideration. I do not advocate the costly system of laying a network of underground perforated pipes through the area to be watered. This is extravagant, unnecessary, and in a few years becomes useless, from the pipes corroding away. All that is required is, first, to see that the drainage is ample, so that there may be no spots where the water can accumulate and become stagnant in the sub-soil; to properly dispose the surface so that the water can be got to flow where required; and then simply to convey it in pipes to the highest points, from whence it can be turned on as wanted, with the assistance of short hose pipes.

T. BAINES (*Field*).

Forcing Seakale.—No better place can be found for this purpose than a Mushroom-house; as, however, many may not possess a house of this kind, it may be well to observe that any structure which will exclude frost will answer. First, a steady bottom-heat of 75 should be secured; secondly, an atmospheric warmth of 60; and, thirdly, total darkness. To these may be added a moist atmosphere at all times, which is an essential point. The roots must be taken up with care; for the less they are broken, the finer will be the Kale. I place them as thickly as they can stand together, and take care to keep their heads or crowns level; I then fill up loosely with very old tan or decayed leaf-soil, as the work proceeds. No water is allowed when they are first put in, watering being reserved for a subsequent operation. The fact is, they require rather a strong bottom-heat at first, to rouse them from torpidity; and this once accomplished, the sooner they are cooled down the better, or the Kale will become "drawn" and inferior. I seldom apply more than one watering, and I infuse a handful of salt in every large water-pot, sprinkling with a little clean water at last. This watering performs three distinct services; it reduces the bottom-heat, it settles the soil around the roots, and by an infusion of salt invigorates the fibres, which by this time are progressing rapidly. If the roots are strong, they will throw up a second "cut," little inferior to the first.—E.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Veitch's Giant Cauliflower, the Best for a Dry Season.—Doubtless others besides myself have had great difficulty in supplying Cauliflowers this summer on account of the drought. I find Veitch's Giant to be the best variety for a dry season. It stands bravely, while Walcheren and many others are literally burnt up.—R. GILBERT, *Burghley*.

Salt for Asparagus. E. B. This is best used in spring, before growth takes place; from 3 to 7 lbs. per square yard may be given. Sea-weed is good manure for Asparagus.

Mont d'Or Butter Bean.—Accompanying this is a sample of the Running Butter Bean, Mont d'Or, which appears to be an improvement upon the Wax Runner, as it is hardier, and also a better bearer. Both sorts were sown here side by side, on the 15th of May last, and the Wax Runner has been nearly a failure, while Mont d'Or has succeeded well, and the quality of the pods is excellent, being quite free from any stringy texture, and tender, even when nearly of full size. The colour is a pale yellow, so that it may almost be regarded as a new culinary vegetable. It requires to be stalked, but its height this season has not exceeded 5 feet.—P. GRIEVE, *Culford*. [The specimens sent by Mr. Grieve, cooked as the French cook the Bean, which they call *Mange tout*, much resembled that vegetable, which deserves to be better known in England than it is.]

THE ARBORETUM.

WISTARIAS AND THEIR CULTURE.

INSTRUCTIONS in growing this family of plants will, to many persons, appear useless. They are so hardy and such rampant growers that success seems assured by simply planting and then leaving them to take care of themselves. This is true enough; but a little art and care bestowed upon them much improves their beauty. When the Wistaria is used for covering the side of a house or for shade to a piazza, some definite system of training should be adopted in so far as to decide what piers or columns of the piazza are to be covered, and whether the plant is to be trained along the cornice or to be carried yet farther upward to screen a window. When this is done and the necessary rods or wires have been provided, the proper shoots for the use required should be selected and thereafter all others that may interfere with the design to be carried out should be rigorously cut away. A system of pruning nearly similar to that of the spur system in Grape Vine pruning should then be adopted, or rather a system combining that with the system generally adopted for fruit trees which bear their flowers and fruits on old spurs. The Wistaria, though a climbing plant like the Grape Vine, produces its flowers from old spurs like a Cherry, a Plum, a Pear, or an Apple tree. In the month of July all shoots or eyes on the main or leading stems that may be reserved, should be pinched back to within a foot of the main stem, in order to check the rampant growth. These shoots will again break into growth from the buds just behind where the shoot was stopped off, and after they have grown a few inches in length they should also be stopped in the same way. The result will be the formation of flower spurs at the foot of the shoot first shortened. Early in the succeeding spring these shoots are to be cut back to within five or six eyes of the main stem, and the young shoots from these eyes are then to be treated in the same way as those of the previous year—and so on, year after year. By following this course of treatment, long continuous wreaths of flowers will be produced. When the leading stem or stems have reached the length it is intended they should attain, they should also be stopped, and the final effect will be an orderly and trim appearance of the plant, which yet, will not appear formal and stiff. Treated thus, the Wistaria may also be grown on the lawn, or as a specimen plant in the shrubbery—either on single stems or as ordinary shrubs with several stems. We grow nearly all our Japanese and Chinese varieties in this way, and no more beautiful objects in the way of shrubs can be had. We have a plant of *W. magnifica* with a single stem about 4 feet high and a cup-shaped head of 8 feet diameter, the whole plant being about 7 feet high, and, just now, a solid mass of fine flowers. We also have specimens of other varieties grown in bush-like form of nearly or quite equal size, each covered with hundreds of racemes of flowers. To our taste, they are far more elegant when grown in either of these forms than when grown as climbers, and the little extra trouble required to produce them thus is amply repaid. Of the Chinese species, *W. sinensis*, there are two varieties, or, rather, the original species with purple flowers, and a variety with light creamy-white flowers. This latter is a rather less rampant grower than the former. Of the Japanese species (*W. floribunda*) there are three varieties besides the original species; viz., the white-flowered, the flowers of which are pure white and the racemes very large; the long racemed-flowered, the racemes of which we have had 32 inches long (not shouldered, as in the other varieties); and the double-flowered, the flowers of which are as double as, and about the size of, a double-flowered Cherry. We have also a variety of another Japanese species, the leaves of which are covered with golden-coloured spots. Its leaves are also smaller and of a deeper green colour than in the two species previously named, and the bark is of a dark cinnamon-brown. The racemes of flowers are much smaller, of a deep purple colour, and the plant is of much more slender growth. We cannot determine what species it is, as we do not find it described in the books. Besides these, we have also received from Japan a very delicate-growing species, the stems of which are not larger than goose-quills. The leaves of this are very small, and the racemes of flowers only 3 or 4 inches long. The flowers are pure white and are produced in July and August. *W. magnifica* is a hybrid variety between the Chinese and the American species. It is a very robust grower. The individual flowers are very large, but the racemes are not as large as those of the Chinese, although more shouldered—an admirable variety to train as a standard. *W. frutescens* is an American species, a native of the Southern States, but quite hardy northward. It is a much more slender grower and blooms much later than the Chinese or Japanese sorts, and on this account we think it better adapted for verandahs. The flowers are of a light purple or Heliotrope colour, and the racemes are about half the size of the Chinese species. There

is a white variety of it, but this is somewhat rare and seldom to be found in nurserymen's catalogues. Besides all these there are *W. brachypoda*, *W. multijuga*, and *W. macrobotrya* to be had from some of our nurserymen. They are all desirable where a large number of varieties or species is wanted, but where only a few are needed the Chinese and Japanese sorts are the best for the garden. [So writes Mr. Hogg in the first issue of his "American Garden." Mr. Hogg, whose garden we had the pleasure of visiting some years ago, has the best collection of these noble hardy climbers we have seen, the best of them being introduced from Japan by his brother. We would especially commend the American fashion of training enormous wreaths of the *Wistaria* from the small gardens of city houses to the top of the house. They embellish the house in a very agreeable way, and yet do not touch it for the greater part of their length, so that the walls are quite free. The bush form also deserves attention.]

GRAND AVENUES FOR LONDON.

MAY I suggest one or two grand London improvements, which might be effected without any serious outlay? The

Hyde Park, in a direct line, a noble avenue of trees, springing from a broad strip of turf, might be established, which would produce a very noble effect—unlike anything else in the metropolis. To effect this, it would only be necessary to sweep away the paltry lines of balustrades and the (so-called) shrubberies of mutilated *Lilacs* and *Privet* bushes, and of irregularly planted trees, stunted by reckless lopping, and establish in their place a fine stretch of simple turf, in which detached trees, at sufficient distances from each other, should be planted. This treatment of the important thoroughfare in question would so greatly add to its apparent spaciousness, and to its beauty, that the value of the property would be at once greatly increased. The last instance we shall allude to on the present occasion as affording a grand opportunity of forming a fine city avenue, is that of the Mall in St. James's Park. To effect the desired amelioration, a few things require immediate attention. First, let the diseased and decaying Elms be removed at once, and as many lines of fine young trees of suitable kinds carefully planted in their places. Some think our opportunities for forming improvements of this

Entrance to the Central Avenue of the Champs Élysées.

first opportunity to be named is that connected with Portland Place and the gardens of Park Crescent. Portland Place is broad enough to allow of planting a line of trees on either side of the roadway, which would give it almost the aspect of a Parisian Boulevard. The carriage-way might, at its northern end, turn to the right and left, as at present; but in a line with its straight portion a broad footway of equal width to the straight carriage-way should be opened through the Park Crescent gardens into the Regent's Park. Such an improvement, if worthily carried out, would be the grandest thing in London; and, as leading almost directly to the beautiful gardens which have been so successfully created on either side of the Chestnut avenue in the Park, would become the most popular and favourite promenade of the West End, and would, in some respects, surpass even the boasted Champs Élysées themselves. Why, the direct opening from Portland Place to the Regent's Park should not have been effected long ago is difficult to account for; excepting that blind and seeming repugnance to any change, which is one of that kind of *Cosus de España* to which John Bull is as completely a slave as the most blue-blooded Hidalgo. Another fine opportunity for a grand Boulevard-like avenue occurs in Westbourne Terrace. From the Bishop's Road to

kind are few in London, whereas the reverse is the case, as, for instance, Oxford and Cambridge Terraces, and many other places that might be named. H. N. H.

TREES IN ASSEMBLAGES.

SOME trees possess but little interest, except they are grouped in masses of greater or less extent. A solitary Fir or Spruce, for example, when standing in an enclosure or by the roadside, is a stiff and disagreeable object; but a deep forest of Firs is not surpassed in grandeur by one of any other species. These trees must be massed in extensive groups to affect us agreeably; while the Elm, the Oak, and other wide-spreading trees, are grand objects of sight, when standing alone, or in any other situation. Groves, fragments of forest, and inferior groups only are particularly interesting in a landscape. An unbroken forest of wide extent makes but a dreary picture, on account of its gloomy uniformity. Hence the primitive state of the earth, before it was modified by human hands, must have been sadly wanting in those romantic features that render a scene the most attractive. Nature must be combined with Art, however simple and rude, and associated with human life, to become deeply affecting to the imagination. But it is not necessary that the artificial objects of a landscape should be of a grand historical

description, to produce these agreeable effects; humble objects, indeed, are the most consonant with Nature's sublime aspects because they manifest no seeming endeavour to rival them. In the deep solitary woods, the sight of a woodman's hut in a clearing, of a farmer's cottage, or of a mere sheepfold, immediately awakens a tender interest, and enlivens the scene with a tinge of romance. Immense forests still overspread a great part of Northern Russia, through which it has been asserted that a squirrel might traverse hundreds of miles, without touching the ground, by leaping from tree to tree. Since the general adoption of railroad travelling, however, great ravages have been made in these forests, and not many years will be required to reduce them to fragments. In the south of Europe, a great part of the territory is barren of woods, and the climate has suffered from this cause, which has diminished the bulk of the streams and increased the severity of droughts. But Nature has established a partial remedy for the evil arising from the imprudent destruction of forests, in lofty and precipitous mountains, that serve not only to perpetuate moisture for the supply of rain to the neighbouring countries, but contribute also to preserve the timber in their inaccessible ravines. Were it not for this safeguard of mountains, the south of Europe would ere this have become a desert, from the destruction of its forests, like Sahara, whose barrenness was anciently produced by the same cause. Most of the territory of North America is still comparatively a wilderness; but in the United States the forests have been so extensively invaded, that they seldom exhibit any distinct outlines, and few of them possess the character of unique assemblages. They are but scattered fragments of the original forest, through which the settlers have made their irregular progress from east to west, diversifying it with roads, farms, and villages. The recent clearings are palisaded by tall trees, exhibiting a naked outline of skeleton timber, without any attractions. Travelling in a forest, though delightful as an occasional recreation, is, when continued many hours in succession, unless one be engaged in scientific researches, very monotonous and wearisome. Even the productions of a forest are not so various as those of a tract in which all the different conditions of wildness and culture are intermingled. A view of an unbroken wilderness from an elevation is equally monotonous. Woods must be blended with other forms of landscape, with pasturo and tillage, with roads, houses, and farms, to convey to the mind the most agreeable sensations.

Colour.

The monotony of unbroken forest scenery is partially relieved in the autumn by the mixed variety of tints belonging to the different trees; but this does not wholly subdue the prevailing expression of dreariness and gloom. A remarkable appearance may always be observed in Maples. Some trees of this kind are entirely green, with the exception, perhaps, of a single bough, which is of a bright crimson or scarlet. Sometimes the lower half of the foliage will be green, while the upper part is entirely crimsoned, resembling a spire of flame rising out of a mass of verdure. In other cases this order is reversed, and the tree presents the appearance of a green spire rising out of flame. We see no end to the variety of these apparently capricious phenomena, which some have explained by supposing the coloured branches to be affected with partial disease that hastens their maturity; but this can hardly be admitted as the true explanation, as such appearances exist when no other symptoms of malady can be discovered. So much has been said and written of late in regard to the tints of autumn leaves, that the writer of this cannot be expected to advance anything new concerning them. Let me remark, however, that these beautiful tintings are not due to the action of frost, which is, on the contrary, highly prejudicial to them, as we may observe on several different occasions. If, for example, a frost should occur in September of sufficient intensity to cut down the tender annuals of our gardens; after this, when the tints begin to appear, the outer portion of the foliage that was touched by the frost will exhibit a sullied and rusty hue. The effects of these early frosts are seldom apparent while the leaves are green, except on close inspection; for a very intense frost is required to scar and roll up the leaves. Early autumnal frosts seldom do more than to injure their capacity to receive a fine tint when they become mature. The next occasion that renders the injurious effects of frost apparent is later in the season, after the tints are very generally developed. Every severe frost that happens at this period impairs their lustre, as we may perceive on any day succeeding a frosty night, when the woods, which were previously in their gayest splendour, will be faded to a duller and more uniform shade, as if the whole mass had been dipped into a brownish dye, leaving the peculiar tints of each species dimly conspicuous through this shading. The most brilliant and unsullied hues are displayed in a cool but not frosty autumn succeeding a moderate summer. Very warm weather in autumn hastens the colouring process, and renders the hues proportionately

transient. I have known Maple woods, early in October, to be completely embrowned and stripped of their leaves by two days of summer heat. Cool days and nights, unattended with frost, are the favourable conditions for producing and preserving the beauty of autumnal wood scenery. The effects of heat and frost are not so apparent in Oak woods, which have a more coriaceous and persistent foliage than other deciduous trees; but Oaks do not attain the perfection of their beauty until the Ash, the Maple, and the Tupelo (a species of *Nyssu*)—the glory of the first period of autumn—have shed a great portion of their leaves. The last-named trees are in their splendour during a period of about three weeks after the middle of September, varying with the character of the season. Oaks are not generally tinted till October, and are brightest near the third week of this month, preserving their lustre, in great measure, until the hard frosts of November destroy the leaves. The colours of the different Oaks are neither so brilliant nor so variegated as those of Maples; but they are more enduring, and serve more than those of any other woods to give character to our autumnal landscapes. It would be difficult to convey to the mind of a person who had never witnessed this brilliant, but solemn pageantry of the dying year, a clear idea of its magnificence. Nothing else in Nature will compare with it; for, though flowers are more beautiful than tinted leaves, no assemblage of flowers, or of flowering trees and shrubs, can produce such a deeply affecting scene of beauty as the autumn woods. If we would behold them in their greatest brilliancy and variety, we must journey during the first period of the fall of the leaf in those parts of the country where the Maple, the Ash, and the Tupelo are the prevailing timber. If we stand, at this time, on a moderate elevation affording a view of a wooded swamp rising into upland and melting imperceptibly into mountain landscape, we obtain a fair sight of the different assemblages of species, as distinguished by their tints. The Oaks will be marked, at this early period, chiefly by their unaltered verdure. In the lowland the scarlet and crimson hues of the Maple and the Tupelo predominate, mingled with a superb variety of colours from the shrubbery, whose splendour is always the greatest on the borders of ponds and water-courses, and frequently surpasses that of the trees. As the plain rises into the hill-side, the Ash trees may be distinguished by their peculiar shades of salmon, mulberry, and purple; and the Hickories by their invariable yellows. The Elm, the Lime, and the Buttonwood are always bleached and rusty; they add no brilliancy to the spectacle, serving only to sober and relieve other parts of the scenery.

When the second period of a fall of the leaf has arrived, the woods that were first tinted have mostly become leafless. The grouping of different species is, therefore, very apparent at this time; some assemblages presenting the denuded appearance of winter, some remaining still green, while the Oaks are the principal attraction, with an intermixture of a few other species, whose foliage has been protected, and the development of their hues retarded, by some peculiarity of situation. Green rows of Willows may also be seen by roadsides, in damp places, and irregular groups of them near the water-courses. One might suppose that a Pine wood must look particularly sombre in this grand spectacle of beauty; but it cannot be denied, that in those regions where there is a considerable proportion of Pines, the perfection of this scenery is witnessed. Something is needful to relieve the eye, as it wanders over such a profusion of brilliant colours. Pine woods provide this relief, and cause the tinted forest groups to stand out in greater prominence. In many districts where Pines were the original growth, they still constitute the larger sylvan assemblages, while the deciduous trees stand in scattered groups on the edge of the forest, and the contiguous plain. The verdurous Pine wood forms a picturesque groundwork, to set off the various groups in front of it; and the effect of a scarlet Oak or Tupelo, rising like a spire of flame in the midst of verdure, is far more striking than if it stood where it was unaffected by contrast. The cause of the superior tinting of the American forest, compared with that of Europe, has never been satisfactorily explained, though it seems to be somewhat inexplicably connected with the brightness of the American climate. It is a subject that has not engaged the attention of scientific travellers, who seem to have regarded it as worthy only of the describer of scenery. I have observed that the Smoke tree, which is a *Sinnach*, from China, and the *Cydonia japonica*, are as brightly coloured in autumn as any of our indigenous shrubs; while the Silver Maple, which, though indigenous to the Western States, probably originated on the western coast of America, shows none of the fine tinting so remarkable in the other American Maples. These facts have led me to conjecture, that this superior tinting of the autumnal foliage may be peculiar to the eastern coasts both of the Old and the New Continent, in the northern hemisphere. May not this phenomenon bear some relation to the colder winters, and the hotter summers of the eastern, compared with the western coasts? I offer this suggestion as a query, not as a theory, and with the hope

that it may induce travellers to make some particular observations in reference to it.

In a natural forest there is a very small proportion of perfectly formed trees; and these occur only in such places as permit some individuals to stand isolated from the rest, and to spread out their branches to their full extent. When we walk in a forest, we observe several conditions which are favourable to this full expansion of their forms. On the borders of a pond or morass, or of an extensive quarry, the trees extend their branches into the opening; but, as they are cramped on the opposite side, they are only half-developed. But this expansion takes place on the side that is exposed to view: hence the incomparable beauty of a wood on the borders of a pond, or on the banks of a river, as viewed from the water; also of a wood on the outside of an islet in a lake or river. Fissures or cavities sometimes occur in a large rock, allowing a solitary tree that has become rooted there to attain its full proportions. It is in such places, and on sudden eminences that rise above the forest level—on a precipice, for example, that overlooks the surrounding wood—that the forest shows individual trees possessing the characters of standards, like those we see by the roadsides and in the open field. We must conclude, therefore, that a primitive forest must contain but a very small proportion of perfect trees: these are, for the most part, the occupants of land cleared by cultivation, and may be found, also, among the sparse growth of timber that has come up in pasture land, where the constant browsing of cattle prevents the formation of any dense assemblages. In the opinion of Whately, grandeur is the prevailing character of a forest, and beauty that of a grove. This distinction may seem to be correct, when such collections of wood exhibit all their proper characters; but perfectly unique forms of wood are seldom found in this country, where almost all the timber is of spontaneous growth. We have genuine forests; but other forms of wood are of a mixed character, and we have rather fragments of forest than legitimate groves. In the south of Europe many of the woods are mere plantations, in which the trees were first set in rows, with straight avenues, or vistas, passing directly through them from different points. In an assemblage of this kind there can be nothing of that interesting variety observed in a natural forest, and which is manifestly wanting even in woods planted with direct reference to the attainment of these natural appearances. "It is curious to see," as Gilpin remarks, "with what richness of invention, if I may so speak, Nature mixes and intermixes her trees, and shapes them into such a wonderful variety of groups and beautiful forms. Art may admire, and attempt to plant and to form combinations like hers; but whoever observes the wild combinations of a forest, and compares them with the attempts of Art, has little taste, if he do not acknowledge with astonishment the superiority of Nature's workmanship." When a tract is covered with a dense growth of tall trees, especially of Pines, which have but little underbrush, the wood represents overhead a vast canopy of verdure supported by innumerable lofty pillars. No one could enter these dark solitudes without feeling a deep impression of sublimity, especially if it be an hour of general stillness of the winds. The voices of animals and of birds, particularly the hammering of the woodpecker, serve to magnify our perceptions of grandeur. A very slight sound, during a calm in one of these deep woods, like the ticking of a clock in a vast hall, has a distinctness almost startling, especially if there be but little undergrowth. These feeble sounds afford one a more vivid sense of the magnitude of the place than louder sounds, that differ less from those we hear in the open plain.

In a grove we experience different sensations. Here pleasantness and cheerfulness are combined, and the feeling of grandeur is excited only perhaps by the sight of some noble tree. In a grove the trees are generally well formed, many of them being nearly perfect in their proportions. Their shadows are cast separately upon the ground, which is green beneath them as in an orchard. If we look upon them from a near eminence, we observe a variety of outlines, and may identify the different species by their shape, while in the forest we see one unbroken mass of foliage. A wild wood is frequently converted into a grove by clearing it of undergrowth and leaving the space a grassy lawn. It may then yield us shade, coolness, and other agreeable sensations of a cultivated wood, but the individual trees always retain their gaunt shapes. As we proceed southward, we witness a constant increase of the number of species gathered together in a single group. Nature is more addicted to the north to the habit of classifying her productions and of assembling them in uniform phalanxes. The painter, on this account, finds more to interest the eye and to employ his pencil in the picturesque regions of frost and snow; while the botanist finds more to exercise his observation in the crowded variety that marks the region of perpetual summer. But while vegetation is more generally social in high latitudes, several families of northern trees are entirely wanting in this quality. Seldom is a forest composed chiefly of Elms, Locusts, or Willows. Oaks and Birches are associated in forests, Elms in

groves, and Willows in small groups following the courses of streams. Those northern trees which are most eminently social, including the two just named, are the Beech, the Maple, the Hickory, the Coniferous trees, and some others; and by the predominance of any one kind the character of the soil may be partially determined. There is no tree that grows so abundantly in miry land, both north and south upon this Continent, as the Red Maple. It occupies immense tracts of morass in the middle states, and is the last tree which is found in swamps, according to Michaux, as the Birch is the last we meet in ascending mountains. The Sugar Maple is confined mostly to the north-eastern parts of the Continent. Poplars are not generally associated exclusively in forests; but at the point where the Ohio and Mississippi mingle their waters are grand forests of Deltoid Poplars, that stamp upon the features of that region a very peculiar physiognomy.

The characteristics of different woods, composed chiefly of one family of trees, would make an interesting study; but it would be tiresome to enter minutely into their details. Some are distinguished by a superfluity, others by a deficiency of undergrowth. In general, Pine and Fir woods are of the latter description, differing in this respect from deciduous woods. These differences are most apparent in large assemblages of wood, which have a flora as well as a fauna of their own. The same shrubs and herbaceous plants, for example, are not common to Oak and to Pine woods. There is a difference, also, in the cleanness and beauty of their stems. The gnarled habit of the Oak is conspicuous even in the most crowded forest, and Coniferous woods are apt to be disfigured by dead branches projecting from the bole. The Birch, the Poplar, and the Beech are remarkable for the straightness, evenness, and beauty of their shafts, when assembled in a dense wood. Some of the most beautiful forests in high latitudes consist of white Canoe Birches. We see them in Massachusetts only in occasional groups, but farther north, upon river banks, they form woods of considerable extent and remarkable beauty; and with their tall shafts, and their smooth white bark, resembling pillars of marble supporting a canopy of bright green foliage on a light feathery spray, they constitute one of the picturesque attractions of the country. Nature seems to indicate the native habitat of this noble tree by causing its exterior to bear the whiteness of snow, and it would be difficult to estimate its importance to the aboriginal inhabitants of northern latitudes. Yellow Birch woods are not inferior in their attractions: individual trees of this species are often distinguished among other forest timber by extending their feathery summits above the level of the other trees.

Pine Woods.

Pines are remarkably social in their habit, and cover immense tracts in high latitudes, extending southward, on this Continent, as far as the very boundary of the tropics, where they are found side by side with the Dwarf Palm of Florida. But in the region of the true Palms the Pine is wanting. Pine woods possess attractions of a peculiar kind: all lovers of Nature are enraptured with them, and there is a grandeur about them which is felt at once, when we enter them. Their dark verdure, their deep shade, their lofty height, and their branches which are ever mysteriously murmuring, as they are swayed by the wind, render them singularly solemn and sublime. This expression is increased by the hollow reverberating interior of the wood, caused by its cleanness and freedom from underbrush. The ground beneath is covered by a matting of fallen leaves, making a smooth brown carpet, that renders a walk within its precincts as comfortable as in a garden. The foliage of the Pine is so hard and durable that in summer we always find the last autumn's crop lying upon the ground in a state of perfect soundness, and under it that of the preceding year only partially decayed. The foliage of two summers, therefore, lies upon the surface, checking the growth of humbly vegetation, and permitting only certain species of plants to flourish with vigour. Fungi of various forms and sizes spring out of these decayed leaves, often rivaling the flowers in elegance. Monotropa, uniting some of the habits of the Fungi with the botanical characters of the flowering plants, flourishes side by side with the showy Cypripedium and the singular Coral-Weed. The evergreen Dewberry, a delicate species of Rubus, trails its glossy leaves over the turf, and mingles its beaded fruit with the scarlet berries of the Mitchella. The Pyrola, named by the Indians Pipsissewa, and regarded by them as a specific for consumption, suspends its pale purple flowers in beautiful umbels. Variety, indeed, may be found in these deep shades; but it exists without that profusion which, in more favoured situations, often benumbs our susceptibility to the charms of Nature. The edging of a Pine wood depends on the character of the soil. The Pitch Pine, that delights in sandy plains, is embroidered at the north by White Birches; and if a road be cut through a wood of this kind, these graceful trees immediately spring up in abundance by the way-side. If a pond occurs in the middle of

a Pine wood, its margin is covered first with low bushes, such as the Andromeda, the Myrica, and the sweet-scented Azalea, then Alders and Willows rise between them and the forest. On the side of the pond that is bounded by high gravelly banks, the margin will be covered by Poplars and Birches. The White Pine, the most noble and the most beautiful tree of the whole Coniferous tribe, predominates in the New England forest; though some wide tracts are covered with the more homely Pitch Pines, which are the trees that scent the atmosphere on damp still days with their delightful terebinthine odours. In still higher latitudes the dark majestic Firs become the prevailing timber, and are regarded as typical of sub-arctic regions, where they are accompanied, as if to form a striking and cheerful contrast with their melancholy grandeur, by groups of graceful Birches, and lively tremulous Poplars.

The Pine barrens of the Southern States are of a mixed character, consisting of the Northern Pitch Pine, the Broom Pine, and the Cypress, intermixed with Red Maples, Sweet Gums, and other deciduous trees. The Pines, however, are the dominant growth; but here they do not grow so compactly as in colder regions, standing widely apart, with a frequent intervening growth of Willows and shrubbery. The sparseness of these woods may be in part attributed to the practice of tapping the trees for their turpentine, which has caused them for a century past to be gradually thinned by consequent decay. Their tall, gaunt forms and almost branchless trunks show that they obtained their principal growth in a dense wood. The first time I entered one of these Pine barrens, was some years since, in the month of June, when vegetation was in its prime, before the summer droughts had seared the green herbage, and when the flowering trees and shrubs were in all their glory. During my botanical rambles in the wood, I was struck with the multitude of beautiful flowers in its shady retreats,—seeming the more numerous to me, as I had previously confined my researches to northern woods. The Phlox grew here in all its native grace and delicacy, where it had never known the fostering hand of Art. Crimson Rhexias, called by the inhabitants Deer Weed, were distributed among the grassy knolls, like clusters of Picotees. Variegated Passion-flowers were conspicuous on the bare white sand that checked the ground, displaying their emblematic forms on their low trailing Vines, and reminding the wanderer in these almost trackless solitudes of that faith which was founded on humility and crowned with martyrdom. Here, too, the Spiderwort of our gardens, in a meeker form of beauty and with a paler radiance, luxuriated under the protection of the wood. Already I observed the predominance of luxuriant Vines, indicating our nearness to the tropic, wreathed gaily over the tall and branchless trunks of the trees: some, like the Bignonia, in a full blaze of crimson: others, like the climbing Fern, draping the trees in continual verdure. These Pines constitute a great part of the timber of the flat country between the mountains and the coast, and render a journey through that region singularly monotonous and gloomy. In the low grounds, a considerable proportion of the wood consists of the Southern Cypress, a graceful and magnificent tree, whose appearance would be very lively and cheerful, were it not for the abundance of long trailing Moss (*Usnea*) that hangs, like funeral drapery, from its branches, and darkens the whole forest. This parasitic appendant wreaths the wood sometimes almost in darkness, especially those immense tracts on the borders of the Mexican Gulf that consist entirely of Cypress. There it has been poetically styled the “Garlands of Death,” as significant of the fevers that prevail wherever it is abundant. It is remarkable that the two extremes of climate are distinguished by the predominance of evergreens in their vegetation. Thus the acicular-leaved trees, consisting of Pines and their congeners, mark the cold-temperate and sub-arctic zones, in north latitude,—while Myrtles, Magnolias, and other broad-leaved evergreens, mark the equatorial and tropical regions. The deciduous trees belong properly to the temperate zones, and constitute, indeed, the most interesting of all arborescent vegetation.—*Atlantic Monthly*.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Good Street Trees.—Mr. J. Jay Smith, of Philadelphia, the originator of the vast and beautifully-designed garden-like cemeteries near that city, recommends the Silver Maple, the Sugar Maple, *Magnolia cordata* and *M. macrophylla*, the Yellow wood (*Virgilia lutea*), the deciduous Cypress, the Kentucky Coffee tree (*Gymnocladus*), *Salsburia adamantifolia*, and the Slippery Elm (*Ulmus fulva*). These are for the most part trees of which we have little experience in Europe.

Lawn Trees.—In selecting trees designed to decorate the lawn, and especially positions clearly within view, care should be taken to select those that retain their foliage fresh until late in autumn. Unfortunately, too many plant some of the early-maturing deciduous trees, which wither away while shade is much wanted. Let us remember that with deciduous trees, their leaves usually commence to fall with the maturing of their fruit, and that exotic hardy trees, such as the Acacia and the Catalpa, bear their leaves perfectly fresh much longer than native English trees.

THE CLOCHE PROTECTOR.

HERE is a sketch of a simple and inexpensive protection for plants, either under *cloches*, as represented, or grown in the ordinary way. The cover is made of bands of straw, interwoven with cord, so as to make a firm mat, 2 or 3 feet in width, and of any length that may be found necessary. At each end of a protector of this kind is affixed a wooden jamb or margin, hinged on to a peg which is sunk into the ground, as shown in our illustration. It will be at once seen that the protector can, by this simple arrangement, be set at any angle, and, from what we know of it, we can recom-

Cheap and effective plant-protector.

mend it as an efficient protector from both cold and sun, and a useful aid in the raising of seeds, cuttings, and tender crops. W.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

The Flower Garden and Pleasure Ground.

CUTTINGS of bedding plants of all kinds may now be generally obtained without difficulty, so push on their propagation with all possible dispatch, as cuttings of any sort put in after this time are generally found to be more difficult to winter than those which have been struck at an earlier period. The various kinds of bedding *Pelargoniums*, which have been some time inserted in pots, pans, and boxes, and placed in the open air, will now be found to be progressing as favourably as could be expected, and should be allowed to remain exposed for some time longer, or as long as it may be found safe to do so. The refreshing dews of night, so long as such nights are not too cold, keep the foliage in healthy condition, and, consequently, favour the emission of roots; mould or damp need not be apprehended while they are fully exposed to air and sunshine; but, as has been formerly advised, the lights of the pits or frames in which they are placed must be in readiness, so as to be easily applied whenever danger is in the least degree to be apprehended. Cuttings of *Verbenas* and other half-hardy bedding plants will yet strike root freely in cold pits or frames, which should be kept quite close for some time, while *Alternantheras*, *Coleuses*, and other tender species may have similar treatment for a week or two, or until the nights become colder, when they must be transferred to a more genial temperature—say not under 60° for some time, or until the cuttings become fairly rooted, when the temperature may be gradually lowered to about 50° as a minimum. Layers of *Carnations* and *Picotees* will now be well rooted, and may be taken off and potted, using light sandy soil for the purpose. Add fresh compost to the piece of ground intended as the site of the Tulip bed, and let this, in the mean time, be turned frequently. Prepare also a bed for offsets; and, with a view to encourage them, give them also a good situation and good soil. Give the necessary attention to “carpet” and other beds in the flower garden, removing decayed leaves and flowers. Mow lawns and Grass belts as frequently as may be necessary; roll gravel walks, and endeavour by every means to prolong the beauty of the parterre as long as possible. Where the removal or transplantation of any large trees or shrubs is contemplated—this may generally be accomplished about the present time, with less danger or risk to the plants, than perhaps at any other period of the year, as it allows ample time for the formation of fresh roots before winter sets in. Damp, showery weather should, however, be selected for such operations; but, failing this, the plants should, in addition to being well watered at

the roots, be well syringed every evening, for some time after being transplanted, and the surface of the soil should be mulched, to prevent, as far as possible, evaporation from the soil. Cuttings of such trees and shrubs as Aucubas, Laurels, of sorts, Privets, Yews, and Roses, may also be inserted now. These should be placed under hand-glasses, on, if possible, a slight bottom-heat, when they will soon root freely; or, where it may be desired to increase any valuable trees or shrubs by layering (a more expeditious method than increasing by cuttings), this may also be done now, and such layers will have time to emit roots to some extent before winter, and this is a considerable advantage.—P. GRIEVE, *Culford, Bury St. Edmunds.*

Hardy Flowers, Alpine Plants, and the Wild Garden.

Signs of autumn are now making themselves evident in the sere and yellow leaf, and the gradual lengthening out of the shadows; yet, as we write, there are occupants of well-selected herbaceous borders just coming into full flower, and others yet to come. These plants have a special value, seeing that ere long the more showy, but tender, denizens of the flower garden will have succumbed to the cold clear nights that usually usher in the harvest moon; then it is that the value of these hardy plants becomes fully recognised. How lovely now are the three autumn Anemones—the old semi-double *A. japonica*, with its deep rosy flowers, so deep as to verge upon crimson, and so persistent of life, as almost to defy eradication; well might the old celestials select it as a fitting plant to decorate the graves of their ancestors. The soft rosy-coloured *Anemone hybrida* bears in its single blossoms the stamp of its parentage from the “Vine-leaved” *Anemone* of the Himalayas, and the pure white *Honorine Jobert*, another of its progeny, equals its parent in purity and rivals it far in size, while it inherits all the vigour, if it does not absolutely excel, in this respect, its Japanese ancestor. The roots of all these produce leaf-buds freely, and by this means these plants may be readily increased; note, however, that they acquire their full development only by long and undisturbed possession. From the Anemones to the *Gypsophilas* is a long leap; it was my intention to follow the established system of classification, but I believe I will feel much more at home as a bee flying from flower to flower, regardless of natural affinities, which, while appreciated by a few, will be of little value to the many. *Gypsophilas*; what of them? All I can say is to know them, is to grow them. In height they vary from prostrate trailing plants (as instanced by *prostrata*, *dubia*, and *repens*), through various gradations (whose names I need not enumerate), to such as *Gypsophila altissima* now in bloom, fully 6 feet high, its pure white blossoms, supported on slender hair-like stems, reminding one of “the starry firmament;” no more useful plant for contributing lightness and elegance to a bouquet than *Gypsophila paniculata*, but its stars have ceased to twinkle nearly a month since. A tolerably close relation to the foregoing is the *Saponaria officinalis*, which, in its double state, is much more frequently met with than in the single; it is, however, like *Horseradish* in the kitchen garden, or *Bindweed* in the hedge-row, a determined monopolist—setting at defiance all the straight-laced ideas of order and regularity—and, though useful in its way, may be induced to run to too great an extent to admit of Nature’s full development of her beauties; therefore, let *Saponaria* have a free and unrestrained corner of the wild garden to itself, and, when planting the old well-known species, be sure to get the variety called *caneasica*; though sometimes called a species, it is nothing more than a dark rosy form of our old familiar friend; both are plants that appear to be independent of drought, and are admirably adapted for the autumns of all time. *Dianthus superbus*, though a Pink, is one that would put a florist into a fever; nevertheless, as all are not florists, there are some, and not a few, who will endorse the fact, that it is a desirable plant for the herbaceous border; its perfume is delicious, especially late in the evening, when the heavy dews, if they do not develop, at least arrest and retain the floating fragrance in the atmosphere. I have a hybrid form of this plant crossed with the *Sweet William*, which is now, as I write, in the full development of a second crop of bloom, and, singular enough, its second floral display arises from the same panicles as the first; but, alas! what it has gained in beauty, it has lost in fragrance. The old species seeds freely, but the hybrid, apparently so satisfied with its own perfection, appears to put a stop to any possibility of variation, as its pods, though fully developed, are always devoid of perfect seeds. From the Pinks to the Mallows is a considerable step, and, possibly, there may be a stepping-stone or two, but at the moment I did not see them, and, lighting on the Malvaceous bank, have seized on the trailing branch of a glorious plant suffused with carmine blossoms, fully 2 inches in diameter—the flowers of *Callirrhoe involucrata*; fortunately, all the Mallows are tough, yielding a large amount of textile material, so we are safely landed amid the family circle. Anything more lovely for a dry sunny bank than this plant can

scarcely be imagined; unfortunately, the whole army of snails and slugs appreciate it equally as much as we do, and, what is more, indulge in their morning repast at an earlier hour than we are wont to be astir; hence, it is apt to suffer from them. Somewhat like this plant in its prostrate habit is the *Malva lateritia*, whose dark green foliage contrasts admirably with its salmon-coloured blossoms; nor is its more exalted neighbour and relation, *Malva Moreni*, to be despised, producing, as it does, a succession of bloom that lasts from June long into the autumn. Its Thuringian neighbour produces larger blossoms, but is more restricted in the period of its floriferous existence. *Erodium Manescavi*, though having done good service ever since the beginning of May, is yet freely producing its large bright coloured blossoms. The best way to increase this plant is by seeds, which it produces freely some seasons; failing such, small pieces of one of the fleshy roots, placed in a gentle heat, will soon emit leaf-buds; these plants have not that vigour of growth such as seedlings possess. Closely related, but more rambling, is the Himalayan *Geranium Wallichianum*, or *Lambertianum* as it is sometimes called—pretty in its dark maroon flowers, its mottled dark green foliage, and its free trailing growth; which latter admirably adapts it to a projecting ledge of the rockery. Amongst the *Flaxes*, we have yet, though the sky blue species have passed away, the bright yellow of *Linum flavum* or *tauricum*, whose property of continuous flowering, compact growth, and perfect hardiness, renders it a valuable plant. *Linum corymbiflorum*, though not hardy, is well worth growing on account of its peculiar battish-yellow colour and the light and graceful arrangement of its flowers. It is of slender growth, and requires to be supported by artificial means. *Francoa*, a Saxifragean genus from the lofty mountains of South America, is one of the few really hardy plants for which we are indebted to the Southern Hemisphere. From the midst of fine massive lyre-shaped leaves rise the flower-spikes, now in full blossom, to a height of 2 to 3 feet; that of *F. ramosa* is pure white, *F. sonchifolia* dark pink, and that of *F. appendiculata* a sort of lilac-rose; these are all readily increased by seeds or cuttings, which root freely in a cold frame. Amongst Composite plants we have many autumn-flowerers; already *Michaelmas Daisies* are in full bloom. Amongst them the abundant-flowering *Aster paniculatus* is a mass of flowers, individually small, but, collectively, very effective; further, it is a nice tufty grower, not a Rambler below ground, nor is *A. spectabilis* to be despised. *A. macrophylla* and *Lindleyana*, though still pretty, have passed their best. Closely allied to the *Asters* is the genus *Callimeris*, of which the woolly-leaved *C. Diplopappus* is an almost continuous bloomer through the summer, and has stood this dry season wonderfully well; its flowers are large, and tinged with a soft lavender tint.—J. C. NIVEN, *Botanic Gardens, Hull.*

Rose Screens.

I find wood to be preferable to wire for screens, inasmuch as when Ivy is employed along with Roses in their formation, the Ivy clings to the wood and forms a more solid screen than wire. I have a screen of this kind between 12 and 14 feet in height; the ground plate is 5 inches by 4, the upright braces and top plate 3 inches by 4, the mesh 5 inches, and the lathes 1 inch wide and $\frac{1}{2}$ inch thick yellow deal. In three years after its formation this screen was one solid looking wall of Ivy, Roses, and Virginian Creeper. This is the season to get such screens made and painted so as to be ready for planting as soon as Roses can be moved. To have a screen well covered in a given time much depends on the ground. It should be trenched 2 feet deep, mixing with the soil, as the operation proceeds, plenty of good rotten stable manure and fresh loam. If the soil is naturally sour in character, the best plan is to have it wholly removed 3 feet wide and 2 feet deep, and to substitute for it good fresh mould of a loamy nature and well-rotted stable manure; and, where brick or lime rubbish can be had, also to add some of that to the soil. This mixture will be found to suit both Roses and Ivy. Ground for screens of this kind is best prepared a month or so before planting, inasmuch as the manure gets more decomposed and more thoroughly mixed with the soil. In planting Roses it is a common practice to dig a small hole, throw in a little manure, and to plant the roots in the manure, leaving the rest to chance. This will not, however, answer in the case of screens, for which both soil and drainage must be perfect, or disappointment will be the result. As to material, use good strong plants of Irish Ivy set 5 feet apart, Virginian Creepers about every 10 feet, and fill in with Roses 18 inches apart. To associate well with Ivy the Roses should be strong growing sorts, such as *Gloire de Dijon*, *Jules Margottin*, *Sir Joseph Paxton*, *Chéné-dolé*, *Acidalie*, *Amadis*, *Glory of Waltham*, *Ophiro*, and similar kinds. *Jules Margottin*, on its own roots, will grow from 12 to 15 feet in height, and it is one of the best of all hybrid perennials in cultivation, both indoors and in the open ground, where I have numerous fine plants of it.—H. G.

Indoor Plant Department.

Sedum spectabile is at present quite a gem in conservatories and similar structures; associated with foliage of *Coleuses*, *Iresines*, and other fine-leaved plants, it has a pleasing appearance. *Salvias*, *Cassias*, some of the late-flowering *Fuchsias*, *Celosias*, ornamental Grasses, and several of the fine-flowered *Begonias* also now show a considerable amount of bloom. *B. Weltoniensis* is one of the best for purposes of general decoration, its habit being good, and it produces a great profusion of bloom, though it does not throw it up very conspicuously from amongst the foliage. Some of the herbaceous kinds, such as *Boliviensis*, look well trained as dwarf standards, especially when the branches are allowed to droop. *Jasminum grandiflorum* is now everywhere in great beauty, and some *Gesnerads*, such as *Nagelias*, *Eucodias*, and *Tydeas*, are also flowering freely in warm corners. Some plants of *Campanula pyramidalis* are also now doing good service; others for later use are placed out of doors on beds of ashes. Sedums for late flowering should be placed at the base of north walls, as should also *Brugmansias* required for later blooming. Pelargoniums for succeeding those at present in bloom should be kept in cool houses rather close, the plants being syringed overhead early every afternoon. Plants of *Solanum Capsicastrum* should be plunged in beds in the open air, where their berries get nicely coloured. *Heliotropes*, *Salvias*, *Sericographis Ghiesbreghtiana*, and plants of like character to be used in the decoration of conservatories hereafter, should also be plunged out of doors. *Plumbago capensis*, one of our finest summer and autumn blooming plants, is now in some places superb. Young plants of it struck from cuttings in spring, and grown on steadily till now, removing all flower-spikes during the summer time, promise to keep up a display of blossom for the next two or three months. *Gomphrena globosa*, too, though apt, sometimes, to damp off suddenly, also comes in useful at this season. *Chrysanthemums* still out-of-doors should have a coating of cow-manure placed on the surface of the pots, applied in the form of a basin, the water descending through which washes down nourishment to the roots. In stoves, plants of *Poinsettia pulcherrima* required for early work should be encouraged by a little bottom-heat and a brisk atmospheric temperature, also by occasional applications of manure-water; some for later blooming should be re-potted into 4-inch pots, and receive cooler treatment. *Euphorbia jacquiniæiflora* should be managed in a similar manner. Some of the *Gesneras*, in the way of *G. zebrina*, *elongata*, &c., are now coming into bloom, and should be supplied with weak manure-water, care being taken not to wet the leaves, as in that case they would become spotted, thus greatly marring their beauty. It is not, however, desirable to have all the *Gesneras* in bloom so early, and in order to avoid this they should be started at different times. Some of the later ones just showing flower should now be potted, using a compost consisting of two parts good yellow loam, one part rotten manure, and a goodly portion of sand. Some use a little turfy-peat in their soil. *Justicias* should now be shifted into a good rich compost. If kept in vigorous health, and free from insects, they soon grow into large specimens, especially if encouraged with a little bottom-heat, weak manure-water to root-bound plants, and occasional sprinklings from the syringe. *J. carnea* is a valuable free-flowering species. We have seen specimens of it measuring 3 feet in height and 3 feet in circumference, and bearing 156 heads of bloom—the third crop of flowers in six months. Some account, therefore, of the treatment by which so remarkable a result was obtained with a plant not unfrequently seen 6 feet in height, with but a tuft of branches on its top, may not be unacceptable. The plant in question was eighteen months old. It was shifted out of a 3-inch pot into a 6-inch pot in August, and in this it was kept over winter till March following, when it was shifted into a 15-inch pot, in which it was flowered. It blossomed first in May, producing ten heads; in July it had ninety-two, and finally it was exhibited on the 5th of October in the condition described. After each respective flowering, the shoots were shortened in, and the plant was placed near the glass in a stove, whose temperature averaged about 65°. With the exception of stopping and regulating the shoots, it received little care beyond ordinary management, but that skillfully applied. The soil in which it was grown consisted of equal parts turfy loam and peat, to which was added a little sand and bone dust. It is, perhaps, but right to mention, however, that after the pot had become filled with roots, and consequently the soil partially exhausted, clear, weak, liquid manure was occasionally administered, which had the effect of preserving the foliage in the most healthy condition, its deep green setting off the fine display of bloom to better advantage, as well as, no doubt, greatly assisting its production. Magnificent as this plant was, however, it had a rival, in the shape of its near ally, *Apelandra cristata*, one of the gayest of stove plants, when well flowered; but, unfortunately, this is seldom the case. The specimen to which we allude was a yard high, and about the

same through, bushy, and bearing twelve glorious heads of bloom, each consisting of from five to fifteen spikelets. This received nearly the same treatment as the *Justicia*. In the same house in which the above were grown was also an enormous *Allamanda cathartica*, which has had from ninety to 100 expanded blossoms on it at one time. This plant had been cut-in very much in spring; it broke strongly, however, and grew rapidly, but did not bloom well till late in July, from which time, until within the last few weeks it has continued in beauty. This plant has been found to delight in a soil composed of turfy loam, mixed with leaf-mould and sand. It should be kept in an airy house during winter—rather dry—and by having the wood well ripened in summer, so as to preserve it from damping off in winter, the plant might be made to bloom a month or two earlier than the one in question, whose treatment might be suitable for succession plants. Such *Gloxinias*, *Achimenes*, and *Caladiums* as have done blooming should be placed in cool houses, and kept quite dry. To those of the two former still in bloom, less water should be given; indeed, it is a good practice to have them all at rest before November, unless there are plenty of roots to spare. Those raised from seeds or leaves this summer, however, should be kept a little moist throughout the winter. Any withered leaves on *Caladiums* should be removed, so as to retain the beauty of the plants as long as possible. Some keep them in a growing condition throughout the winter, but that is not desirable.

Indoor Fruit Department.

Where the wood of Vines is brown and hard to the apex, and the Grapes ripe and well coloured, little fire-heat will henceforth be required in late Vineries. Admit abundance of air on fine days, and the temperature may be allowed to fall to 40° on cold nights. Keep the atmosphere sweet and dry, so as to prevent damping and improve flavour. Outside borders attached to houses in which Grapes are hanging should now be protected from excessive rains; for, where the borders are saturated with wet, Grapes seldom keep well. Shanking, too, which is the most destructive of all diseases to which Grapes are liable, is greatly promoted by encouraging superfluous moisture about the roots. Tared thin deal shutters, 6 feet wide and 10, or 12 feet long, placed so as to incline towards the front of the borders, form the best of all protectors; they last in good condition for many years, and they can be conveniently removed in spring, and stored until the following autumn. When in use, they should be elevated on bricks 3 or 4 inches above the surface; a circulation of air is thus kept up about the border, which assists greatly in keeping it dry. Thick tarpauling serves the same purpose as shutters; but I prefer the latter. Straw thatchings are sometimes used; but they are apt to retain moisture. Pines swelling fruit should be supplied with abundance of weak guano-water. As regards succession plants, slightly decrease the atmospheric moisture, that they may harden their growth sufficiently to withstand the vicissitudes of the coming winter. Keep the temperature for these and for fruiting plants at 85° during the day time, and 70° at night. In the case of newly-potted suckers, see that the bottom-heat does not get below 85° or above 90°. Shade them from bright sunshine, and keep the atmosphere of the house or pit in which they are growing close and moist. A damping overhead, early on clear afternoons, prevents the leaves from withering until roots have been formed. Queens intended for early fruiting, will now require very little water, perfect rest being what they need for two months. Keep the temperature for these at 60° during the night, and give plenty of air during the day time; on all favourable occasions let a free circulation of dry air pass through Peach-houses. Thin the leaves from about late fruit, and assist their ripening by means of a little fire-heat. Fig trees which have been grown in pots in warm houses, and which have been cleared of their crops, should be removed outside, and set in some sheltered corner, where they should receive a vigorous syringing by means of the garden engine, to clear their foliage of dust and insects. Keep the temperature about growing Cucumbers up to 70° at night. Young plants produced from seed sown a month ago will now be ready for planting out of pots into an open compost of loam and well-decayed manure. Sulphur any parts on which the slightest indications of mildew are visible. Water Strawberries in pots with liquid manure, and otherwise give them every possible assistance to enable them to produce strong fruitful crowns.—J. MUR, *Clovenfords*.

Out-door Figs.

Figs out-of-doors are mostly a good crop in the eastern counties, and wasps are becoming very troublesome to them. One plan of baffling the wasps, is to gather the Figs before they are fully ripe, and lay them on a shelf or raised sieve in an early Vinery to mature. The latter is the best method, because the warm air surrounds and reaches all parts of the fruit; besides, in laying such a fleshy fruit as the Fig flat on its side on a shelf, we invite decomposition. But for

the extra labour involved, I should much prefer hanging up each fruit by its stalk. Either way, by gathering and storing in safety a few days before they are ripe, we remove a great temptation out of the way of the wasps, and save our Figs. Wasps, and even birds, are much more easily managed and mastered when they are not allowed to taste our best fruits; for this reason, I never leave decayed fruit exposed to their ravages. A second method is placing the fruit in bags, which should be large and stiff, so as to hang clear of the fruit, if not, the hungry wasps light on the sides of the bags and forthwith proceed to clip their way through with their mandibles. When the bags hang loosely they buzz round and round, and at last wheel off in despair. Bags of wire gauze would be preferable to muslin or stiff cheese-cloth for this purpose. Enthusiastic amateurs sometimes bottle their Figs, using wide-mouthed bottles, and blocking or corking them in; these not only protect the fruit from danger, but hasten maturity; and, in fact, furnish each fruit with a glass-house all to itself. It would take, however, very wide-mouthed bottles, indeed, to hold Brunswick Figs, which are particularly large this season. The quality, too, is remarkably fine, more delicate, juicy, and, in fact, superior in lusciousness and flavour to the Brown Turkey, or almost any other Fig grown in the open air. It is quite a mistake to stop the shoots of out-door Figs, at this season, to hasten the ripening of the fruit. Such stoppings have little, if any, effect in that direction, and do their best to destroy the crop for next year. It is a mistake to assume that when a growing shoot is stopped, the strength that was devoted to the extension of its parts, must necessarily be diverted into the ripening fruit. It is far more probable that the strength will be arrested altogether, by stopping growth which at least drew a full supply of vital fluid past the base of the fruits. But the greatest evil of stopping autumnal growths in Figs arises from the operation stimulating the young Figs in the axils of the leaves of the stopped branches to swell beyond the limits of safe wintering. What those limits are is not very clear, but a safe principle to act upon is the smaller the fruit the safer. Stopping, enlarges them, and, consequently, is an evil. Most of the protective means adopted to keep large Figlets on the trees to ripen next year fail. There is no difficulty in wintering them; but when exposed in the spring a late frost stings them through their hearts, and the sudden change of condition causes them to drop. Hence, for years past I have given up protecting Figs, and trust to a crop, that has seldom or never missed, from the small Figlets near the extremities of the shoots. No frost injures these, which, indeed, are hardly visible, and are, I presume, too much sheltered and wrapt up to be hurt by even the most severe cold.—D. T. FISH.

Kitchen Garden.

In most gardens at this season there are usually numbers of spare pits or frames, some of which should now be prepared for Lettuce and Endive, so as to have a supply under cover in the event of sharp frosts occurring in October or November. Pits which have been used for Cucumbers or Melons, if the manure is not immediately required for digging in the land, will require to have the soil on the top thoroughly stirred, all roots taken out, and, if dry, moistened, so as to have it in a thoroughly healthy growing condition. In thus making provision for autumn and early winter salads, every one, of course, must be guided by the demand they will have to meet. It is advisable, however, in planting a pit of several lights to select plants of different ages and sizes, for the sake of the successional character such a mode of planting will give—thus a light or more may be planted with half-grown plants that have been once transplanted, and the remaining space filled with the smaller and later sown plants. It will be found a better plan to plant now, where they can easily be protected when necessary, half grown plants (as the check given in moving them will be an advantage rather than otherwise), than to wait, as is commonly done, till frost is apprehended, and then hastily take up large full grown Lettuces, and stow them away thickly in frames, where the most careful management often fails to preserve in them that full flavour and succulence generally observable in plants that retain all their roots until they are required for use. I should, however, say that Endive is much more manageable in this respect than Lettuce. As regards varieties of Lettuces for winter, the Bath Cos should always be one of the varieties grown, and the Tom Thumb Cabbage, owing to its excellent flavour and quick growth, is also a very useful variety. Referring again, for a moment, to the question of transplanting: since the recent copious rainfall very rapid growth is observable in all kinds of green crops, and a certain grossness or over-luxuriance is not unlikely to take place, which will make them less able to stand a cold winter. This tendency can at any time be checked by partially lifting each plant with a steel fork; and wherever Broccoli are planted too thickly, half the plants may be lifted to form another

plantation, and, probably, the transplanted plants will turn out the most satisfactory crop. There is no occasion to use any protection to Lettuce in frames at present; give them all the air possible, and it would be as well to have stored somewhere a quantity of dry wood-ashes, or dry dusty peat, to scatter round and amongst the plants when the short damp days arrive, to counteract any tendency to damp or mildew. Mustard and Cress should be sown under hand-lights during the present month, after which it will be as well to sow in boxes in a warm house or pit. Steady fires will now be required in Cucumber-houses and pits; a night temperature of 65° with a bottom heat of 75° is quite high enough, if the plants were planted early enough to come into bearing by the time they will be required. Do not stop the leading shoots till the top of the rafters is nearly reached, and the plants will gain immensely in strength and vigour, which will all be required before the winter is over. Stop all side shoots one joint beyond the fruit, and dis-bud rather than prune if there is likely to be a superabundance of growth. If the hot-water pipes are fitted with evaporating pans (as they ought to be) keep them full of soft-water. Too much moisture at this season tends to produce soft watery growth, while too little is sure to bring on red spider and other ailments. The character of the weather must therefore in some measure guide both the application of artificial heat and moisture.—E. HOBDAY.

The Queen's Park.—The directors of the Artisans, Labourers and General Dwellings' Company have obtained a site of 80 acres in the west of the metropolis, on which the work of erection of a new city, to accommodate no fewer than 16,000 persons, is about to be commenced. The plans have been already drawn up and the roads marked out. This new city will be constructed on the same general principles as those which have been carried out on the Shaftesbury Park Estate, and no stronger evidence of the necessity of the work can be found than the fact that already, when not a single brick has been laid, applications for upwards of 1,000 houses have been made. The scheme has received the approval of the Premier, and, in fact, of all the distinguished personages who take an interest in the progress of the movement for providing suitable homes for the working classes. The share capital of the company, which was £250,000, has all been taken up, and is now increased to £1,000,000. The estate will be called the Queen's Park, and, like Shaftesbury Park Estate, it will be made as attractive as possible. Four out of the 80 acres will be appropriated in the centre to a garden and recreation ground; the roads and streets will be planted throughout their entire length with trees, and special inducements will be offered to the inhabitants to lay out the gardens both front and back in as tasteful a manner as their time and means will permit. These inducements have hardly been found necessary at Shaftesbury Park, for, long before the announcement was made that prizes would be offered for the neatest forecourt or best show of flowers, the inhabitants had been vying one with the other in these respects, and during the past summer thousands of persons have visited the estate as much to see the various displays of flowers as to view the houses. The general style of the architecture in Queen's Park will be the same as that adopted in the estate at Clapham Junction, and there will, of course, be all the usual accessories to a town with a large population. The lecture-hall and institute will be a large and imposing building, and there will be co-operative stores, coal depot, dairy farm, baths and washhouses, and other buildings. The estate is near the Harrow Road, from which it will be approached, and there is constant communication with the district from various parts of London both by omnibus and rail. The foundation stone will be laid next month, when the work will be put in progress; but this ceremony will be purely formal, as it is intended to ask Her Majesty to lay the memorial stone early next season. There is to be no public house on the property, and like the estate at Shaftesbury Park, every opportunity will be taken to promote and develop temperance principles. Reading rooms, discussion clubs, libraries, and other substitutes for the public-house, will be a marked feature.—*Times*.

The Gardens of the New Workmen's Cities.—Sir,—In reading the gratifying announcement about the Queen's Park in *The Times* of this day, it occurred to me how much better the little gardens would look if the wretched network of garden dead walls were abolished altogether. These shut out the light and air, and help to make town gardening more difficult than it need be. Besides, the appearance of the whole district will be very much injured by these walls, which are as evident in the new Shaftesbury Park as in any quarter of London. Everybody who passes out of London by rail must have noticed the dismal effect of these walls, forming, as they do, a kind of shallow well in which children and plants have a poor time of it, so far as inhaling the fresh breeze is concerned. If it be determined that separate gardens are best under the circumstances, surely it will not be impossible to find some fence or hedge that will be less objec-

tionable than these unsightly walls. Is it not a pity that the "flat" system is not adopted in these cases? The bane of London as a city is that it is in great part covered with mean houses with no sufficient space between for roads, walks, or trees. By the intelligent adoption of the "flat" system room could be found for all these necessities, and four times the number of people could be healthfully lodged on the same space of ground.—W. R., in *Times*, Sept. 17th.

BIRCHES AND ASPENS.

LOOKING out from my window upon the dark sides of the mountains, upon the massive clouds, upon the wind-blown trees, I see my pet, the Birch, all in a shiver with each blast. The American white Birch has all the grace and delicacy of its European namesake, and, besides, a sensibility which it borrows from the Aspen, or shares with it. One should have, near every country house, a group of Aspens and Birches. Planted together, they will give you motion in charming variety. On other trees the leaves are so rigid in the stem, that a wind strong enough to set them in full activity is strong enough to set all the branches in motion. We recognise the force, and, in large trees, the grandeur of motion. When a strong wind moves the whole tree, it swings its great boughs hither and thither, all its leaves and twigs utter their voices, which in chorons often rise to a roar. Yet, though the whole tree is agitated, and seems convulsed, one sees that it is only upon the exterior; while the top and sides are in full motion, the trunk stands firm, and seems motionless. Not till its very roots give way will it move, and then it does not bend, but goes down with stiff trunk. The elastic Birch, with long and slender limbs, avoiding horizontal positions and aiming at the zenith, flexible to the last degree, moves in the wind with a grace and elasticity which has no parallel. The American Aspen has a shivering leaf upon a rigid branch. It stands quite stiff and motionless in bough, while its leaves are quivering and shivering in the most industrious manner. Aspens are my wind-meters, or, rather, zephyr measurers. On a hot noon, when no air seems stirring, and the trees about them doze and slumber, like good men at church, these twinklers, like roguish boys, are dancing in an imaginary breeze, and playing with themselves, without a particle of wind, so far as I can perceive. Now a shiver runs over them from head to foot; then the topmost leaves shake and swirl, while the bottom rests. Gradually the motion dies away all over, and the frolic ends. No, a single leaf begins to wag; it goes on in single blessedness, with accelerated pace, up and down, round and round, until, for the life of me, I cannot help bursting into a fit of laughter at this solitary dance. At times, in certain moods, one cannot help thinking that the Aspen is striving to communicate something. It seems to sigh and pant. It supplicates as one that suffers. Then, changing suddenly, it coaxes and winks and blinks at you as if it was only in fun. It will stand perfectly still a minute as if looking to see what you will do, and then a laughing ripple runs all over it. It frolics with the same tireless grace as a kitten. Indeed, it is a kind of compound kitten-tree, each particular leaf a kitten, all frolicking together; though there is not one of them, if the rest won't play, that is not really, kitten-like, as it were, to chase its own tail. Why have landscape gardeners done so little with Birches and Aspens? Maples, Oaks, Ashes, and evergreens are very well; but in what other direction shall we look for such grace in form, such susceptibility to aerial influences, and such exquisite motion of both branch and leaf, as we find in the Aspen and Birch? The Birches grow rapidly, are extremely hardy, and will flourish upon poor soil, though loving a generous soil better. In ten years, with Birch and Aspen, one may rejoice in a thick grove. If the yellow Locust be added to these, and the silver Maple, one who plants at sixty may hope to see, high over his head, a respectable young forest, dense enough for shade and high enough to begin to comfort the imagination. Long live the Aspen and the Birch! Only the young have just grounds for prejudice; but even boys soon outgrow the Birch, and watch its sinewy motion without a thought of moving, too, in shivering accord. H. W. BEECHER.

Effect of the Californian "Rattleweed" on Cattle.—According to the *San Francisco Chronicle*, a plant called "Rattleweed" is producing a most destructive effect upon horned cattle. The "Rattleweed" grows to a height of about 18 inches, and has a leaf similar to that of a Lupine. It has an immense number of pods, which are of a light brown colour when ripe, and of a three-sided form, like the Brazil nut. These pods do not crack open when ripe and dry, and as every pod contains half a dozen or more small loose seeds, it forms a rattle, producing, when touched or moved by the wind, a clear sharp sound, resembling the warning of the rattlesnake. It is found—sometimes in small detached clumps, and sometimes in patches covering many acres—in Kern, Tulare, Fresno, and Monterey counties, and in the northern part of Los Angeles. The effect of this

weed when eaten by animals is to produce insanity, or, to speak more accurately, it appears to derange and "befog" their instincts, and, judging from their actions, fills them with delusions. When thus affected many of them die, but whether death is the direct effect of the poison, or whether it results from their inability to procure water and food, is, as yet, unknown. Several hundred horses have lately died from the effects of this weed in the southern part of Monterey County, and a correspondent of the *Chronicle*, who lately lost fifty horses on one rancho from the same cause, describes the symptoms that were apparent in the ill-fated animals previous to their decease. They became (he says) too muddled to seek for water, and many of them died of thirst. Although they were wild and had never been handled, any person could walk up to them on the plains and hit them with the hand, when they would jump, perhaps straight up in the air, perhaps some other way, and go off as though they were trying to leap over a fence at every step. They seemed to retain their sight, yet would not turn aside for anything.

Trees in Printing-house Square.—*Appropos* of the imaginary difficulty of growing trees in London we may mention that in passing the *Times* office the other day with Mr. Charles Moore, Director of the Sydney Botanic Gardens, we were both much pleased and surprised to see two unusually good specimens of the North American Shubby Trefoil (*Ptelea trifoliata*) in perfect health. We have not seen better specimens in any botanic garden, thus affording another proof of what we have often expressed, *i.e.*, that deciduous trees are as easily grown in London as anywhere else.

The Pelargonium Society.—Dr. Denny is right in saying that Mrs. Turner and other Pelargoniums with large trusses of flower are too good to be grown out-of-doors; we do not want all Pelargoniums for bedding purposes; on the contrary, pot-culture is quite as essential in many cases as bedding. The time will come, and is, indeed, not far distant, when Pelargoniums will play a conspicuous part in greenhouse and conservatory decoration, blooming, as they do, the greater part of the year. In order to encourage size of truss, shape, colour, &c., I would suggest that prizes should be awarded for a single cut truss of the largest dimensions, in various classes and colours. Also that prizes be given for the best thirty-six dissimilar blooms (cut), twenty-four ditto, and twelve ditto. Also prizes for the best six cut trusses, new, or not in commerce. They should be shown in stands similar to those in which Dahlias are shown. This would greatly add to the number of exhibitors.—EDWARD BENNETT, *Hatfield, Herts.*

Competitive Examinations.—"Examinations are such as in a great measure to mar the main intention of the work of education. The examinations involve impossible attainments on the part of students. A burden is laid on them heavier than they can bear. The result is cram-work and failure. They know something of everything, but little thoroughly of anything." "Within four years students have to overtake, and are presumed to master, a large number of subjects—any one of which might well be the occupation of a life. The sad, the disastrous thing for students, is, that the range or measure of the pass examinations on every branch is co-extensive with the whole literature of each. The examinations are indefinite—undefined; they are whatever examiners choose to make them; and examiners are not always discreet. They have their whims, their fancies, their hobbies. Not seldom they carefully get up the night before (and from big books on their shelves) for examination purposes on the morrow, what they themselves will forget directly the examinations are over. . . . A student may pass with credit at one board and yet be rejected by another." Sir Robert Christison is reported to have said that nothing is easier than to reject a candidate trained at a different school from that of his examiner. Students have now no time for original thought and research—the only real proof of merit. The examinations "leave no time for aught save cram-work with the grinder." . . . "It is sometimes said—and in a boastful way—that the attainments of students in these days greatly exceed those of the students of former days. In a certain sense this is true. But what if these attainments are proportionably shallow—fragmentary, a mere smattering of things?"—"Syllabus of Materia Medica."

A Peach Stealer.—A Worcester boy was engaged in nocturnal Peach-stealing a short time ago, and was observed by the owner of the fruit, who, unnoticed by the young robber, placed a large stuffed dog at the foot of the tree, and retired to watch the result of his strategy. The boy, descending, observed the dog, and then the fun commenced. He whistled, coaxed, threatened, unavailingly, the animal never moved. And, finally the youth, accepting the inevitable, settled down to passing the night in the tree. After some hours had passed wearily enough to the lad, morning dawned, and the proprietor of the tree, coming from the house, asked him how he came to be in the tree. To which the boy answered that he took it to save himself from the dog, who had chased him for a long distance.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare*.

ENJOYABLE GARDENS.

SHALLOW people have sometimes wondered how Lord Bacon, who was a philosopher, statesman, and lawyer, should have thought it worth while, in his "Counsels, Civil and Moral," to introduce an essay on gardens. What, they ask, have gardens to do with things civil and moral? The first lines of the essay itself justify its place among moral themes. A garden was first planted by our Creator, "and, indeed, it is the purest of human pleasures; it is the greatest refreshment to the spirits of man, without which buildings and palaces are but gross handyworks." In Bacon's time Puritanism had not turned old English heartiness sour, nor stigmatised pleasure and the love of it as sinful weakness of the flesh. Refreshment for the spirits of man was yet held an allowable and even praiseworthy thing to aim at. Pleasure ranked among supremely moral matters, as we are once more beginning to see, though perhaps there is a less intelligent apprehension than one could desire of the true ingredients of the best kinds of pleasure. If we look at the popularity of gardens, for example, it is plain that men have not yet, as a rule, in England acquired a just taste for this purest of human pleasures. At Sydenham, where there is one of the most delicious gardens possible, in its own style, the gardens draw less by a thousand times than a Shah of Persia, or an acrobat wheeling a barrow along a rope. Even people who really plume themselves on their passion for gardens are constantly found, perhaps in the majority of cases, actually not to know what a garden is, and to believe that a passion for gardens means a passion for acres of Grass with countless flower-pots and endless supplies of heated air underneath. A man with a true love for gardens, when he goes down into the country to stay with somebody with a great reputation for flowers, knows by this time what he has to expect, and how little his own taste will be pleased. It is not the gardener but the glazier whose glories he is taken to see. Horticulture is a misnomer for viticulture. Instead of a ramble along green-sward in the free air, laden with fresh scents, he traverses weary miles of glass-covered walks of brick, in an artificial and languorous atmosphere, surrounded by flower pots and water-pipes. The whole thing is only a shade less distasteful and tiresome than a laboratory. Perhaps, in addition to this enthusiasm for glass, the host has a passion for Latin names, which he insists on inflicting on men who neither know nor care about the niceties of floral classification. This horticultural pedantry is particularly disgusting, because it really gives no single atom of instruction, and has no single element of suggestive knowledge about it to those who have not been trained in the subject. And you mostly find, too, that the horticultural amateur who is most tediously particular about his Latin names for things, has the least possible knowledge of the general ideas that belong to the study of botany. His knowledge is all empirical: it has no growth in his mind, and only consists of a bundle of detached and disconnected labels. Botany, rightly studied, is one of the most instructive and useful, as well as one of the most delightful, of all the concrete sciences, because it is so simple and so perfect an example of a truly scientific classification. But your fine horticulturist, all glass and Latin as he is, extracts as little as possible of the true worth of his study from his vast legions of flower-pots and specimens and labels. One wonders why these people, who bore one to death with the special names of this flower and that, do not insist on letting you know the exact name of the Grapes, Strawberries, and Cherries at dessert, all in botanical dog Latin. Of all impostors, viticulturists seem to be the most egregious. They are endured, and their tribe waxes more numerous, because they offer a good opening for that vulgar ostentation which is so charming a feature of our society. You can spend an immense sum of money in glass, and flower-pots, and hot air. *Argal*, they contain the one essential of right

pleasure. Into Bacon's conception of a garden, it is true, though he asked for thirty acres of space, the glass-house did not enter. But then, in his time, the measure of the refreshment of spirit which men could get out of a garden or a house was not simply the amount of money which could be put into it. We are so much wiser now than the Elizabethans. What Elizabethan ever made £100,000 in a single year by luck in dry goods? For moderate men thirty acres of space are usually much more than they can command for a garden. Gardening on a large scale is costly in the labour which it requires, even if land were cheap, which it certainly is not. You may have ample "health and sweetness" in tinier plots than thirty acres, provided your garden be not surrounded by high brick walls in the old and perhaps also the modern manner. Even with them one may not fare very badly. There are some charming old gardens in the Twickenham and Hampton country, though they are mostly as rigidly enclosed within four walls of brick as the parlour or the sleeping-room. In a sense, gardens of this narrow and curtailed size and sort are in the nature of apartments of the house, and very gracious and pleasant chambers they are. Even in those wildernesses of houses which are spreading far and wide in the suburbs of London and the other great centres, the little square spot at the back door is not laughable, judged from a proper point of view. It is not a garden in the sense in which Hampton Court Palace or Kensington has gardens, any more than the rooms are rooms compared with the saloons of the palace. But it is an open-air chamber in which, of a summer evening, a man and his wife may delude themselves most agreeably and profitably into the notion that they survey the loveliness of Nature and the marvels of Creation. Why should they not? There is not nearly so much illusion in these humble delights as there is in the costlier delights of more ambitious folk. Still let us agree that narrow and walled spaces, with flowers, and strips of turf and gravel, are not gardens in the truest sense, in which gardens deserve to have all good things said of them. For these, space is essential; but, then, it is not indispensable that the space should all lie within one's own private and particular domain. A fair and wide prospect is as much mine as if I held the fee simple of every acre. The "magic of property" may make an ugly bit of land fair; but a man must have fallen into a bad way if he finds a fair view from his window ever cloudy and loveless, just because he does not possess the parchment title to it. Granted that your morality in this respect is sound, to acquire for a garden all that a Bacon could ask in it, the one thing needful is to plant it on a height looking over a spreading weald, or down into a pleasant valley; or to place it in a prospect of distant hills and downs. In such a case it matters not a jot whether the garden be thirty acres or half an acre. We have no need of Bacon's six acres of "heith or desert" in the garden, if there are miles of heath on any side of it; nor of his four acres of green in the entrance, if there are grassy downs within a mile or two. If rightly placed, a garden, to be full of delight, need be no more than a broad and ample piece of well-kept lawn, with flower borders and fragrant hedges. All that you want a soft and pleasant carpet for the feet, little pieces of bright colour for the eye, gracious prospects, and the perfume of Honeysuckle, Thyme, and the like. There must be also a sheltered walk with gravel for the winter days and nights. But it is a vile blunder to cut a garden up with gravel walks, which are pleasant to no sense. And the worst of it is that in not one garden of a hundred are those walks broad enough for three persons to be abreast with full comfort. People unaccountably prefer a couple of narrow strips to one broad alley. And it is hardly a less blunder to take up space with craftily-devised flower beds, or many cunning combinations of form and colour. As Bacon says of the similar knots of figures in his time, "You may see as good sights many times in tarts." For the main point in a garden, if it is to be for the great refreshment of the spirit of man, is simplicity. The simpler it is the fewer chances are there of its getting out of order, and so disturbing the eye and mind of its possessor. To idle men who have nothing better to do than to make the garden a business, this will not count. But to busy and absorbed men, the avoidance of every slight root of irritation and the corresponding gain of serenity are worth anything. Nor are complex and artificial pleasures ever really

soothing. They may distract or divert, but the use of a garden is that it diverts without stimulating. It composes the mind, even in the midst of the gravest cares, to a wholesome passivity. The anxieties of the world, cares of business, excitement of politics, are reduced and paled in a man who can enjoy the sweetness of a homely garden. But a garden that is a show place, or the imitation of a show place, is no more refreshing to the spirit of a sensible man than the sight of a ball-room crowded with beauties and dandies. [There is a considerable amount of truth in the above from the *Pall Mall Gazette*. The reference to Sydenham, however, where an "acrobat or a Shah of Persia" draws so much more than the gardens, makes us add a few words, to point out how much our public gardens are deficient of the very qualities to which the writer clearly enough sees, are the vital ones. We quite agree that "it is a vile blunder to cut up a garden with gravel-walks, which are pleasant to no sense;" and it is equally bad to cut up the surface with other things; look, for example, at a plan of the Crystal Palace gardens, and see how the whole central parts of the landscape is destroyed by vast fountain-basins. And look at Leicester Square, or, indeed, any of our new London public gardens, and you will find the surface cut up in the most important parts by walks, mostly needless. The planting or the bedding-out complete the confusion, and destroy all repose.]

WINTER GARDENS AND AQUARIA.

WE shall soon have various excellent opportunities for the formation of winter-gardens, Ferneries, indoor rock-gardens, &c., in connection with the rather numerous aquaria now being got up, and it is to be hoped these will be taken full advantage of from a gardening point of view. Partly in consequence of the great success of the Brighton aquarium, and partly from other causes, the rage for such structures is rapidly spreading. As it is a fashion which leads to one of the most wholesome sources of pleasure—the gratification of interest in the hidden beauties of Nature, it can scarcely spread itself too widely. Fish life, and submarine plant life, had been mysteries to the general public till the first attempts at aquaria lifted a corner of the veil which had so long covered the secrets of the sea. The revelations, though so scanty, were yet so interesting, that the attempt thus to popularise a knowledge of ocean life became at once a success, and miniature aquaria, with sea Anemones and nest-building sticklebacks, were to be found in numerous dwellings. The large dimensions of recent aquaria, from those of Paris to those of Brighton and the Crystal Palace, have opened up a far more extensive and instructive vista into marine life than hitherto existed; though, looking at the matter from the gardeners' point of view, marine plant life has not at present been sufficiently attended to and illustrated. Still, sufficient has been done to arouse public attention very remarkably, and we consequently hear of projected, or even already progressing, aquaria in many quarters. Winter gardens, too, have at last started suddenly into public favour, and excited almost as much public interest as the popular aquaria themselves; indeed, we now generally hear of winter gardens and aquaria as twin structures, more than one of which is now promised in London itself, which has been, up to the present time, somewhat behindhand in such matters. From the point of view assumed by *THE GARDEN*, terrestrial winter gardens are, of course, more important than aquaria. During the long winter months Londoners have no pleasant promenade in which a lounge can be enjoyed in the midst of flowers and green foliage. The Crystal Palace is too distant for a very numerous and yet very appreciative class; while the noble Palm-houses and other plant buildings at Kew are rather suited for the purposes of study than as areas in which winter promenades, in the midst of vegetation, can be enjoyed. In several parts of London it has been more than once proposed that spacious winter gardens should be established; but such proposals have, till now, found neither sufficient seconders nor the ways and means to carry them into execution. At last, however, an announcement has come forth from the "Royal Aquarium and Summer and Winter Garden Society," stating it to be their intention to establish a marine aquarium on a large scale in Westminster;

and also a winter garden. Even another London aquarium is proposed, having for its site the Thames Embankment, doubtless to be combined with a winter garden. With such decided successes in view, as the aquarium at Brighton and that at the Crystal Palace, it appears somewhat singular that the metropolis should have remained so long without a marine aquarium and winter garden of dimensions and general importance worthy of our great and wealthy city. Some have endeavoured to account for the delay by the distance of London from the sea; but with our present engineering knowledge at command a daily supply of sea-water either for marine baths or aquaria present but comparatively trifling difficulties, and we hope at last to see such difficulties triumphantly overcome, and that marine aquaria upon a larger scale than anything hitherto attempted, may be successfully established. It is the scale, in fact, that marks the difference between a mere toy and a structure that may command the admiration and approval of our greatest naturalists, as forming a school of instruction in a very interesting branch of science, by means of which many important questions may be solved.

H. N. H.

THE WASTE OF WATER.

IT is not without cause that the long drought, from which we have at last a prospect of being relieved, has turned the attention of cultivators to the singular one-sidedness of our dealing with that element we have so long felt the want of. Water is a good servant, but a bad master, and in our elaborate and persistent struggle to emancipate ourselves from the mastery, we forget the service, and find ourselves destitute. For the living generation, nothing has been talked of so much in this country, as how to get the water off the land as quickly as possible. Old people may, perhaps, remember exactly when this national hydrophobia first showed itself, but it certainly was aggravated by a series of wet summers, early in the century, conspiring with circumstances which made Wheat almost the exclusive object of attention. The first maxim of British husbandry was—"Look to the Wheat harvest for your profit," and the laws said the same thing; so it followed, as a matter of course, that water was regarded rather as the enemy of the Wheat crop than as the friend of the pasture, the flocks, and herds. Everybody who has had to do with land, has been mulcted a good per-centage of his income for drainage of all kinds, surface, deep, and arterial, as if water were simply a curse, and never a blessing. For fifty years the towns situated on rivers with low banks, have been complaining loudly that, whereas the waters formerly came down sluggishly enough, giving them a damp month at a time, and rendering the meadows marshy, they now come down at short notice, in a three days' deluge, leaving them soon dry as before. Of course, there was much to be said on both sides of the question as regarded the towns; but it has become evident that both sides of the question have to be considered in the case of the country too. Four-fifths of the hay crop of this year were lost; what remained was a mere raking, which it was pitiable to look at as the chief provision for our cattle in the winter. Of course we were promised a rainy August, a lingering autumn, a mild winter, and an early spring, with abundant root-crops; but all the farmer sees are a few ricks which would not stand a month's siege by his usual stock. Meanwhile, in by far the greater part of the country, there is water not only within reach, but fully at command. There are streams, or springs, or wells, or wells easily made, or a surface favourable for the collection of the water. Sometimes, in more than one place in a single field, there will be spots where water settles, or where it oozes out, and which, consequently, the tenant regards as running sores to be cured by the miraculous touch of the landlord. Yet nothing is ever done to husband that which sometimes is found grievously wanting. In no country in the world that an ordinary tourist sees is there less provision or method for the collection and distribution of water. Here and there, where Nature almost compels, there are water meadows, often as old as the Romans; but, under ordinary circumstances, no one ever sees canals for irrigation, tanks for irrigation, or devices for raising water to such a level as shall command the surface. A windmill for this purpose, a steam-engine, an hydraulic ram, a bucket-wheel, or any of the simple devices to be found even among African savages, would be thought a madness here. In fact, nothing is done to supplement the defects of Nature, except on a small domestic scale, and as expensively as possible. Generally we allow even our gardens to be ruined by the first drought, unless we can spend a fortune in water-towers, piping, steam-engines, and skilled workmen. We cannot remember to have seen at any of our exhibitions—international, agricultural, floricultural, industrial, or cottage—any simple contrivances for

raising water within the scope of small people. Apparently, it is easier to drain a lake than to water a kitchen garden. In many cases all that is to be done is to get the water hoarded or raised to an elevation dominating the ground to be watered. A locomotive engine would do it much more easily and cheaply than is commonly supposed. Fire-engines are not constructed for this purpose, but only to shoot the water as high as possible; yet they throw hundreds of tons in a few hours. It is only a question of management to make power do its work. A London housemaid thinks nothing of going to the top of a four-story house twenty times a day. A proper application of that power would raise a ton of water 20 or 30 feet, and in the course of a twelvemonth would most thoroughly irrigate even more than half an acre of garden. Now, everybody, from the master of the house downwards, if he be in health, has superfluous strength to keep down. Nature itself tells him that, and accordingly he goes forth several times a day, in the impulse of muscular irritability, to do some work or other—to walk a mile, to dig, to chop, to prune, to plant, to destroy. Boys, especially, want an object, and do not much care what it is. Now, why cannot our mechanists make some simple kind of apparatus whereby this strength, instead of going to waste, may prevent water from going to waste? The usual way of raising water from a well in this country is very wasteful of strength. It does not employ the whole body or the whole weight. A woman with great effort raises a bucket, we will say, ten times a day, and in so doing she raises, not a ton of water, nor half a ton, nor a quarter of a ton, but only half a quarter—that is two hundred weight and a half. The same consideration applies to the sanitary arrangements of decent houses. Forcing pumps are a very costly and laborious method of raising water—that is, when it is raised by human power. T.

THE CHRYSANTHEMUM.

THE cultivator who looks ahead is now hard at work at the Chrysanthemum, a plant that will keep his houses gay from October to December, and so carry him over one of the gloomiest periods of the "plant year." The Chrysanthemum is a plant that everybody, even to a child of a London court, may be said to be acquainted with. This is because it is blessed with a decidedly strong constitution. It can be grown almost anywhere. In the public gardens of London, where other plants appear to be half choked with soot and grit, it may be seen sprouting vigorously; in the window of the mechanic's dwelling in a London street it seems to fare best of all, and almost beats the Fuchsia, that king of window plants. The ways and methods of cultivating this plant may be termed legion. The rough-and-ready plan of rearing it for market and for cut flowers is to strike cuttings in a hot-bed early in April, and directly they have struck harden them off, pot into large 60's, and plunge the pots up to their rims, and directly they have got tolerably well rooted pot them into large 48's, and flower them in these pots. If the plants have been judiciously pinched, and never allowed to suffer from dryness, they will by the latter end of October present a vigorous head of bloom. This, however, is a very rough way of rearing them; for, although they flower well, they will not bear the appearance, health, or size of a well-cultivated plant. To have a well-grown Chrysanthemum suitable for the conservatory stage, robust cuttings should be taken from the old plants about the first week of April, and placed two in long thumb pots which have previously been filled with well-mixed soil of loam, leaf, and sand, with a good coating of sand on the top. The cuttings should then be dibbled in and plunged in a frame on a good fresh dung bed. Many advocate an ordinary propagating frame, but the dung bed will be found more suitable, as giving to the plants the moist warm atmosphere that is so essential to them, and which often secures them from the attacks of red spider, &c. If the cuttings have been carefully put in, they will, in a day or two after, present a healthy appearance, being upright, and wearing a fresh green aspect. For the next fortnight they should be gently syringed and kept shaded, with only just a slight amount of air on, which should, however, be widened as the plants appear to gain strength. In about sixteen or eighteen days the pots will be well filled with roots. Then, choosing a warm genial day, remove them to an ordinary cold pit, and, placing them evenly in the ashes (or tan), keep the pit closed and shaded till they recover, when they should, for a day or two, be gradually exposed to the sun and air, and at last have the pit-lights off together during the day, except when it is cold and wet. In a fortnight from their removal from the dung bed they will be quite ready for their first shift, which should be potting each cutting, or rather by this time young plant, singly in large 60's, using one part loam, one of sand, and two of leaf mould, and, if obtainable, one of horse filings, which will strengthen the plants perceptibly. Having got settled in their fresh pots, they must be exposed at every favourable opportunity, and have plenty of water, and once a week liquid manure, rather

weak. About this period they may have their first pinch. This is a process that must be carried out with care, as on it depends the shape of the plant. The first pinch must be so as to allow the plant to start with four good robust leaves; and this will cause the plant to shortly bristle with side-shoots, which, when fit to handle, should have their tops taken off, and so on until the middle of July, when the pinching off shoots should be discontinued, and the plant allowed to grow freely. Towards the end of May the plants can be shifted into large 48's, and again plunged in the frame, taking care to give them plenty of room, and in another fortnight they will be fit for large 32's; in this shift plenty of horse filings should be mixed in the soil. About the middle of June, or earlier, if the season is warm, they can come out of the pit; and, choosing a nice hard piece of ground exposed to the sun and rain, a bed of coal ashes can be made up on it and the plants plunged. By this time they will have attained a good size, and, through the pinching, will have a supply of vigorous branches, so that particular care should be taken to give them copious waterings and syringings, and about twice a week a good dose of strong manure-water. All July they will be growing very hard; and about the first week of August, when a good many of the garden hands can be got together, give them their final shift into 16 pots, getting them done as quickly as possible, so as to keep them at the same stage of growth. They should be again plunged, and will want nothing more than plenty of water till the end of the month, when they should be staked, which should, of course, be performed so as to have the plants round and uniform, the tall branches in the centre, with the smaller ones round the outside; and this plan will be found to be one of the best and simplest to show up their beauty. It is best to get them into a spare greenhouse about the second week of October, just before the first frosts come. The Chrysanthemum is a plant that is better without heat; yet, by this, I do not mean that it should be exposed to cold and damp, but that a temperature of 45° or 50° will keep it in health when blooming. This plan of growth will answer about the best of all, when there is a big conservatory to fill; and it is a plan that with ordinary care will seldom fail to give satisfaction. The one important thing to bear in mind in rearing this plant is, that it is a vigorous feeder—it may be indeed called a thorough gourmand; it therefore can hardly be overfed, and, in addition to the horse filings, some good manure might be mixed with the soil. Of the Anemone-flowered kinds I would recommend Antonius, Emperor, Prince of Anemones, Astrea, and Lady Margaret. Of the Japanese varieties, Bronze Dragon, Prince Satsuma, and Tassel Yellow. Of Pompon varieties, Mrs. Dix, Helene, Aigle d'Or, and Rose Trevenna. Of the ordinary crimsons, Albion, Dr. Sharpe, Captivation, and Sam Slick. Of the lilacs, Fingal, Venus, Ossian, and Lady Slade. Of the yellows, Gloria Mundi, Golden Nugget, Yellow Perfection, and Golden Queen of England. Of the whites, Beverley, Mrs. Geo. Randle, and Virgin Queen. These are mostly old varieties, but, nevertheless, they are well-tried ones, and will, perhaps, give greater satisfaction than the more modern productions. G. G.

Highgate.

Proposed Changes in the Botanical Gardens, Hull.—At a recent meeting of the Cottingham Local Board, it was mentioned that Councillor D. P. Garbutt, of the Hull Town Council, intended laying out for building purposes an estate of 230 acres just outside the borough and adjacent to the park. The proposed drainage for Cottingham, near the estate, is to be enlarged, and six or seven boulevard streets constructed, drains filled in, trees planted, and work done at a cost of about £80,000. The estate is to be called the Westbourne Park Estate, and in the boulevards are to be "circuses" with fountains. Mr. Garbutt has offered to take the present Hull Botanical Gardens at a valuation, and to sell from 20 to 30 acres on the new estate on reasonable terms.

Japanese Mulberry Trees.—When a people contrive to make saucepans, fine pocket handkerchiefs, and sailors' waterproof coats out of paper, they may be considered to have mastered a useful art, and this is demonstrated by the above articles of Japanese manufacture, with the additional little circumstances that the saucepans are generally used over charcoal fires. According to their own account, these ancient islanders wrote upon silk faced with linen, and also used very thin wood shavings for the same purpose, until nearly the third Christian era. About A.D. 280 paper was first imported from the Corea, and, superseding the home made fabrics, monopolised the market until the year A.D. 610, when the King of the Corea sent two priests to Japan to establish the manufacture. This paper was easily torn, and liable to be destroyed by worms, and, besides did not take the ink well. These manifold disadvantages attracted the attention of Taishi, the son of the reigning Mikado, who substituted as material the bark of a species of paper Mulberry, which is still extensively cultivated for the purpose.

NOTES OF THE WEEK.

— MESSRS. GARCIA, of Covent Garden, have sent us some specimens of huge Walnuts, which weigh, as they are gathered from the tree, $1\frac{1}{2}$ to $5\frac{1}{2}$ ounces each. They were grown at Teddington by Mr. Vanderlynden, and are well flavoured and, in other respects, perfect fruit of their kind.

— It is scarcely worth while to pollute the air of the London parks by burning weeds in them, as is now done in Kensington Gardens. Those who take the otherwise pleasant walk from the Queen's Road, Bayswater, to the western end of the "Row," and in doing so have to pass through clouds of offensive smoke, will, probably, agree with us, that a few waggon-loads of wood-ashes are dearly bought at the price of such a nuisance.

— We are glad to notice a great improvement in the way in which plants are labelled in Hyde Park. The circumlocutory, and almost useless, numbering system has been done away with, and a really good pattern of iron label, so written that it can be easily read, has been substituted. The only slight blemish now is, that many of the generic names are contracted thus—Pelar. for *Pelargonium*, and so on. For the sake of the general public, it is desirable to avoid such awkwardness, especially as nothing is gained by it as regards expense.

— A SPLENDID specimen of the Dove Orchid (*Peristeria elata*), is just now bearing six or seven fine spikes in the Royal Exotic Nurseries, at Chelsea. This is the finest specimen of this plant which we have ever seen. In the same establishment we also noted a richly blotched and large-flowered form of the chaste *Odontoglossum Roezlii*, the blooms of which are even finer than those represented in the last number of Bateman's "Monograph."

— A LOCAL paper reports a great abundance of fruit in Gascony. The trees and Vines, it says, are so loaded, that the branches threaten to break down. Peach, Plum, Apple, and Pear trees have had to be propped up. Peaches, weighing three to the pound, are being sold in the streets of Toulouse at 6d. a dozen, and fine Grapes at 1d. per pound. In the country, 100 Reine Claude Plums can be bought for 1d. or $1\frac{1}{2}$ d.

— A LETTER was read on September 11th, at the Paris Academy of Sciences, on a particular toxic action exercised at a distance by *Colchicum autumnale*, at the time of flowering. The hand, when held near the anthers of the flowers, without coming into actual contact with them, changes in a few seconds to a livid greenish-yellow colour. The natural colour returns about ten seconds after the removal of the hand. The author believes that this remarkable action is chiefly exerted during or near the period of fertilisation, and proposes to examine further the nature of the substance emitted.

— COLEMICUS, and other hardy autumn-flowering bulbs, are just now very beautiful in many gardens and nurseries near London. In Messrs. Osborn's Nursery, at Fulham, we recently saw nice clumps of *Colchicum autumnale*, *C. album*, *C. multiplex*, *Sternbergia lutea*, and the beautiful deep blue *Crocus speciosus*; while, elsewhere, we have seen fine masses of the *Belladonna* Lily and the vivid scarlet *Schizostylis coccinea*. In Mr. Rucker's garden, at Wandsworth, too, we recently saw a splendid specimen of the noble *Crinum* expense, flowering freely in the open air, in a position which it has occupied for several years.

— A FLOWER show has been held at Salt Lake City, at which the fruit, flowers, and vegetables, are reported to have been excellent. Dreary as is the aspect of the deserts of Utah, fine products are obtainable there by the aid of water; and when we visited the "City of the Saints" in 1870, the Vines, Tomatoes, and Apples, looked as promising in the gardens of Brigham Young and Brother Jennings as in most other parts of America. A novelty in the way of prizes seems to have occurred to the Salt Lakers. "A basket of flowers proffered to the young lady under eighteen years of age who could tell the most names of the different flowers on exhibition, was awarded to Miss Sarah Ann Walker, daughter of Mr. D. F. Walker, who gave the names of eighty-one of the varieties.

— THE "Heatherside Manual of Hardy Trees and Shrubs," a copy of which we have just received, deserves more notice than we usually bestow on such trade lists. It is alphabetical in arrangement, and forms a useful dictionary of most of the hardy ligneous plants in cultivation. Its value, too, is especially enhanced by both common and botanical name being given, and it is all the more welcome because it is one of the first attempts that have been made to make a trade list a really useful manual of reference; for, many besides ourselves must often have experienced considerable difficulty in finding the names of even common plants in ordinary lists. For instance, *Arbutus*. Are we to look for it under the head of shrubs or of evergreens, or by its English name of Strawberry tree? Or the Larch. Is it to be found in ordinary catalogues as a deciduous tree or as a Conifer, or by its English name, Larch, or under the head of

forest trees? and with plants that are less known the difficulty, of course, is greater. In the Heatherside manual much of this uncertainty is removed, and the result is a catalogue that should find a place in every garden library.

— IN the corridor at the Royal Exotic Nursery, Chelsea, there is a plant of the White *Lapageria* now bearing about 310 of its beautiful flowers.

— WE understand that Mr. Max Leichtlin's collection of *Lilium dalmaticum*, recently obtained by him in Montenegro, together with other bulbs, has passed into the hands of the New Plant and Bulb Company, at Colchester.

— IT is to be regretted that some of our leading botanists and scientific men (generally so hard on anything tinged with the sensational) have been themselves of late indulging in a little clap-trap at the meetings of the British Association and elsewhere. A notable instance of this is the so-called "Carnivorous Plants," a name in itself a piece of "sensationalism" of a very poor type. There is, no doubt, much that is curious in these interesting plants, many of them long well-known in good collections, and the keenest observers are well employed in studying their peculiarities; but it is much to be regretted that statements about them should be made which are quite unjustifiable by the facts of the case. The cuts in last week's *Graphic* follow the same cue. A state of things is there depicted which (and all those who know the plants well will testify to the truth of what we say) is quite beyond the facts. But it is when we come to read the description of the illustration, that the results of recent British Association teaching may be best seen. "As our readers will see by reference to the engraving, these plants are furnished with various kinds of traps or snares for the noway insects upon which they live. The *Sarracenia*, the large plant on the left of the page, the *Nepenthes*, in the centre, and the *Cephalotis*, which is immediately below it, have lids which shut down upon their victims. The *Darlingtonia*, shown on the right, curls its leaf around them; the *Pinguicula*, in the right-hand bottom corner, shuts itself up and curls its leaves; the *Dionaea* on the left beneath the *Sarracenia*, also shuts itself upon its prey, and the *Drosera*, in the left-hand bottom corner, has an arrangement of fine lines ending with little knobs, which it throws over its prey, and thus secures it." There are several statements in this short passage which are not merely doubtful, they are wholly false. We refer more particularly to the "lids which shut down upon their victims," and to the assertion that the "*Darlingtonia* curls its leaf around them." This is ridiculously untrue, as we can testify, from having spent many days in one of the habitats of the plant in California. We also agree with Mr. Andrew Murray, who, writing in a contemporary, says, referring to "the digestion of the fly or albuminous matter by the plant. I cannot believe in feeding without a mouth, or digestion without a stomach. We are not dealing with an amoeba, but with an organism whose operations Dr. Hooker compares to those of the human stomach. His position is, that it digests 'the same substances, and exactly in the same way, that the human stomach does.' As to the substances being the same, it comes to nothing. There are two agents at universal work all over the world, engaged continually in dissolving what can be dissolved—the stomachs of animals, and the agents of natural decay; their action is similar, and their powers limited by the same bounds. But when we come to the plant digesting in exactly the same way as the human stomach does, I am entitled to ask—where is the apparatus by which it does so? Had he said in some way analogous to the operation of digestion in a sponge, or in a foraminifer, I might have, from my ignorance of how they do it, been forced to hold my peace; but when the human stomach is given as the type, I am entitled to ask—where is the apparatus for digestion? Something more than gastric juice is needed for that purpose—where are the complicated apparatus of epithelial cells, the follicles, the villous coat, and all the means of assimilation? It is perfectly plain that Dr. Hooker only uses the comparison with the human stomach as analogous and not identical; and even here he will scarcely deny that, put it any way he likes, the analogy is of the feeblest. Again, assuming that there is such an apparatus, although we cannot discover any trace of it, or anything different in the minute analogy of *Dionaea* and *Pinguicula* from that of any other plant, I think it is fair to assume that it will be a complicated apparatus—seeing that the supposed commencement of the operation is on the pattern of the human stomach, and the histological arrangement of the human stomach is extremely complicated. Would it not be an anomaly in the economy of Nature if a complicated apparatus should be provided to do something which is of no advantage to the plant, and which it seems to be able to do quite well without? Of course there are no flies for the *Pinguicula* to feed on in winter, and yet it grows as well then as in summer. For three weeks of the time I observed, we had a great deal of rain, and the leaves were washed free from all remains of flies—yet the plants seemed to thrive better and better."

ASPECTS OF VEGETATION.

(LANDES OF GASCONY—FIXING BLOWING SANDS.)

WHEN we think of the aspect of the Landes of the south France, our mind sways between two images, one, the aspect of the Landes a hundred years ago, when they were a mere barren waste of shifting sand, that was daily invading the cultivated land in the interior, and the other, their present wooded appearance, as shown in the accompanying woodcut.

It was M. Bremontier, an able officer of the French administration of forests, who, in 1789, devised the means by which these barren shifting sands have been fixed and converted into their present form of profitable forest. Their previous condition, as described by him, and quoted by Loudon, consisted of drifting sands, which covered 300 square miles. The surface of this immense tract was like a sea, which, when agitated to fury by a tempest, had been suddenly fixed and changed to sand. It offered nothing to the eye but a monotonous repetition of white wavy mountains, perfectly destitute of vegetation; a multitude of round tops, some of them scooped out so as to resemble craters or semi-circular mounds. In

wish to bury me? I feel myself already oppressed with the weight of this sifted sand, which thou throwest at me playfully; yet, at the same time, it seems as if it would re-awaken me to life, whether it comes from the warm sea, still impregnated with marine odours, or whether it descends from the dune, all balmy with the pollen of flowers." And she thus graphically describes the Landes from another point of view:—"The moving rampart of sand, 40 leagues in length, notwithstanding its mobility, seems inexorable. Not the smallest harbour exists. The great waves coming from America beat against the outline of the desolate shores. If they accumulate sand and *débris*, they do not mould them in opposition to, or in accordance with, the dunes, like the ocean and the Gironde. The rivers which flow from the interior have gradually been constrained to yield to the dykes thrown across their channels. They flow parallel to the sea, in a southerly direction, so as to pour into it obliquely their dwindling waters." This is the scene shown in our woodcut. The river is fenced from the sea by a long bank of sand, now bearing the trees planted by Bremontier. It is an old story how he did so. The difficulty of fixing shifting sands is no

Present aspect of the Landes of Gascony.

imes of violent storms of wind, the surface of these downs was entirely changed; what were hills of sand often becoming valleys, and the contrary. It was on these occasions that the sand was carried up into the interior of the country, covering cultivated fields, villages, and even entire forests. This used to take place so gradually (by the sand sweeping along the surface and thus raising it, or falling from the air in a shower of particles, so fine as to be scarcely perceptible), that nothing was destroyed. The sand gradually rose among the crops, as if they were inundated with water, and the herbage and tops of the trees appeared quite green and healthy, even to the moment of their being overwhelmed with the sand, which was so very fine, as to resemble that used for hour-glasses. Madame Michelet in her recent work, "Nature; or, the Poetry of the Earth and Sea," incidentally shows that its character, in this respect, remains unchanged. She says:—"The sun was already high in the heavens. Feeling somewhat fatigued, I flung myself back upon a sand-hill; nor could there be a softer bed. The sand was so fine, so mobile, that though the wind was light, it felt about me like an impalpable dust. But soon my dress was full of it, and even my hand was covered. This set me dreaming. Wherefore, oh charming Nature, do'st thou

new problem, and various have been the means resorted to. But none have succeeded so well as Bremontier's. He sowed, on the surface of the sand, seeds of the common Broom, mixed with those of *Pinus Pinaster*, or Cluster Pine (var. *maritima*), one of the few Pines that thrive in sandy soil. He commenced on the side next the sea, or on that from which the prevailing wind blew, and sowed in narrow strips at right angles to the wind. The first strip was protected by a line of hurdles; it, in its turn, protected the second, the second the third, and so on, until the whole breadth of the downs, in the locality with which he was dealing, was covered with plantation. His success was complete—the barren waste of sand is now clothed with the fragrant Pine. Charming open sandy spots invite the traveller to pause and take shelter from the rays of the hot sun under the thick foliage of its giant boughs. A flora of its own has supplanted the previous lifeless desolation—a flora meagre, but exquisite and rich in pungent penetrating perfumes; Vervain, Mint, Bindweed, Marjoline, and Broom are scattered around. A fauna, too, has followed in its train; crowds of insects that prey upon the Pine have swarmed after it, and their hum adds to the rural charm of the scene. Everything breathes of solitude and repose; Nature herself seems asleep, but not dead.

Before Bremontier, on such a day and such an hour, she might, indeed, have seemed dead; but, now, life is all around; man himself breaks the charm of apparent lethargy; the sound of the woodman's axe breaks upon the silence; the blue vapour of the charcoal-burners' heap ascends into the sky, and assails the nostrils. Thanks to Bremontier, man has found here, too, something for his hand to do; women and children have followed in his train, and the blowing, shifting, restless sands now yield subsistence to an industrious, though scanty, population.

A. M.

THE FRUIT GARDEN.

INDOOR GRAPE CULTURE.

THE following is intended chiefly to be an answer to Mr. Andrew Murray's inquiry (see p. 172) respecting the failure of Mr. Jennings's Grape Vines at Salt Lake City. Mr. Murray does not say whether the sorts are American or European, but I presume they are the latter, as I know of no instance in this country, in which native Grapes are grown under glass, except in cases of propagation. European Grape Vines are useless for outdoor culture in the northern and middle states, owing to their liability to mildew, and even under glass it is only an experienced cultivator who can guard against its attacks. The "slender puny" character of Mr. Jennings's Vine canes I neither attribute to cold, soil, or transplanting, but to want of water, particularly if the soil is light. Our summers differ materially from those in England: here sun and wind soon rob the soil of its moisture, and as the Vines naturally start late, the drought often begins just as they are bursting vigorously into growth; what then can be expected but partial failure? A few pottfuls of water will not do; the border, outside and in, should be forked loosely and roughly, and a thorough soaking given. Yes, barrels of water are needed. Afterwards, roughly level the surface, and mulch it over some 3 or 4 inches deep with litter. During the summer months, until the fruit begins to colour, give thorough soakings of water over the litter, say, once a fortnight, or oftener if the weather be very dry. I know an instance, near Boston, in which some Vines planted against the wall of a lean-to Vinery were rather neglected in the way of water last year; they, therefore, made scarcely any wood, but this year, on being flooded, they have produced immense rods, that promise well for next year's crop. Mildew attacks unhealthy Vines sooner than it does vigorous ones; but in any case, it is so destructive and abundant in this country, that we cannot ventilate by means of the front sashes one day, without finding mildew the next; and, even in the case of top ventilation, we must use caution, as too large an amount of fresh air from that source is equally productive of mischief. Now, this a hard matter, as the sun sometimes shines fiercely in the morning, and unless we ventilate, and that early, the leaves get scorched. I begin to think that Mr. Wm. Thomson's plan, of compelling front ventilation to pass over the hot-water pipes, is an excellent one, and much more necessary in this country than in England. I have not, however, seen a single instance in which it has been put into operation here.

Red spider is another desperate enemy to our Grape Vines, especially where root or atmospheric drought is allowed to exist, even for a short time; and, if once this pest is permitted to get a footing, it defies all attempts to eradicate it. The clear dry air and hot sun favour its development, and it travels quickly from Vine to Vine, spinning webs and breeding with alarming rapidity, the result being rusty leaves, incapable of yielding any support. Nor does this little pest disappear with the leaves; on the contrary, it buries itself in the folds of the stem-bark, and in every crevice where shelter is afforded it. This necessitates the stripping off of all loose bark in the winter, rigidly washing the stems with soft-soap and water, and afterwards painting them over with sulphur mixtures. The house, too, should be thoroughly washed and cleaned, and all *debris* burned. We must, at least, start with clean Vines and houses, syringe twice a day, and maintain an atmosphere saturated with moisture until the Vines blossom, and from the time they set fruit till they begin to colour, the syringe must be in constant use. This, to a certain extent, is contrary to English practice; but this climate demands such attention. Greenhouse plants here are commonly grown, more or less, in Vineries, and from these meanly bug escapes to the Vines, disfiguring the appearance of the fruit. Rigid cleanliness, both of house and plants, and killing, by means of bug-brush and syringe, using a little Abyssinian mixture, are the best remedies. Some consider that European Grapes may be grown well in cool Vineries here—that is, houses without fire-heat; but I entertain a different opinion. Such late houses would furnish Grapes when our markets were glutted or well stocked with native fruit; and hence

they would not be of much value, except for the sake of variety, besides, late Vineries neither yield the amount of crop nor quality of Grapes grown in heated houses. We have a very large Vinery here, containing black and Victoria Hamburgs, Wilmot's Hamburg, Golden and Muscat Hamburgs, Muscat of Alexandria, Buckland Sweetwater, Frontignans, and others, which we force, so as to have ripe fruit towards the middle of July, and in this house we manage to have healthy Vines, excellent berries, a fair crop, and bunches weighing from one to five pounds each. In another Vinery of the same dimensions, containing some of the Vines just mentioned, together with Lady Downes, Alicante, Trebbiano, &c., but, without any means of heating, there is an equally well-set crop, just colouring; but the berries are small, and none of the bunches weigh a pound—indeed, the average might be set down as 5 oz. or 7 oz. Both houses were planted at the same time, four years since, and the Vines made good wood; except those in the late house which are deficient of both wood and leaves. In growing Grapes under glass in this country, the Vines should be started briskly, and, when once set a-growing, should be pushed on vigorously till their growth is made and their fruit is matured. Fire-heat I consider necessary in order to start growth kindly, bring out the blossoms equally, and to set the berries properly, as well as assist their swelling and ripening. The wood, too, must be well ripened, and judicious management exercised at setting and stoning times, and in lessening inside moisture, and leaving a little ventilation on all night at ripening time. In most cases here the Vineries are kept at greenhouse temperature during the winter months, on account of the plants which they contain. In other cases, however, as in that of Mr. Jennings, where there is no heating apparatus, there is danger of injury from frost. In that case the Vines should be unfasted from the roof, laid on the ground, and covered a few inches deep with dry soil, ashes, or sand. The border over the roots, especially outside, should be mulched, and when a snow storm comes all should be left undisturbed until a thaw occurs, when the snow should be shovelled off, otherwise the cold water will sink into the soil, doing much harm, inasmuch as it retards early root action. Wooden shutters, oiled canvas, tarpanlin, &c., might be used for covering borders in winter, but these are not in all places come-at-able; only the other day I saw some promising young Vines cut back considerably by last winter's frost. The Vinery in which they are growing is span-roofed, and the rods being ripened early are turned outside and buried in the border on the approach of winter, to permit the Vinery being used as a forcing house for cut flowers, but last winter they were insufficiently covered, and consequently suffered from frost. Mr. Jennings, I think, should thoroughly soak his borders at starting time and keep the roots and atmosphere damp during the summer season; he should never allow laterals to get crowded nor strip off a large quantity at any one time, but do so gradually; the Vines should be syringed, but not forcibly, with tepid water every afternoon, from the time when they begin to grow until they flower, when syringing must be discontinued; but it should be resumed when the berries are formed, and continued till the fruit begins to colour. Whitewash the outside of the glass with hot lime-wash, in which some glue has been dissolved, after the plants have begun to grow strongly, removing it when the fruit is cut. This prevents sun-scorching. Both bunches and berries should be liberally thinned, and, in the event of a heavy crop, that should be done in good time. Ventilate at the top of the house; but not at the sides till the fall, when both top and front sashes may be left open night and day. On the approach of winter, prune the Vines, but do not shorten them too much, and then bury them inside the house; or, in the event of that being impracticable, roll up the canes in dry mats or other protecting material, after having unfasted them, and thus leave them till February or March, when they should be undone and started when required. If the house is heated unfasten the Vines and let them bang. Artificial heat at setting time is of immense importance. I may add that gardening in the New England States bears no resemblance to that in England. Apples thrive well, and Pears in some places, but in others Pears are subject to canker and are short-lived. Peaches used to be grown some twenty years ago in perfection in Massachusetts, but now, owing to repeated failures, they have been entirely discarded. Raspberries and Strawberries do well, but require covering with soil or leaves in winter; otherwise they would be killed. Red and White Currants are extensively grown, and are quite hardy; but it is a rare thing to find a Black Currant. I do not think Americans like them. Blackberries (Brambles), with fruits fully an inch long, bear heavy crops, but they require caution in picking, as the fruits are black some time before they are fully ripe. Native Grapes are planted largely in gardens and fields, and they may also be found in the woods. They bear heavily and in most years ripen well, but the Grapes are not appreciated much by Europeans owing to their foxy flavour. Cottagers here are very fond of their garden plots, in which

they grow Petunias, Asters, Zinnias, Phloxes, Sweet Peas, Nasturtiums, and Morning Glory; Paeonies, Pansies, variegated Balm, and Pinks. They have also some scarlet Pelargoniums, that they strike in autumn and winter indoors, and a great variety of pretty blooming shrubs, such as *Deutzia crenata* and *gracilis*, Mock Oranges, Yellow Currants, Lilacs, Fringe trees, Smoko trees, Tulip trees, which bloom splendidly here, *Weigela rosea*, *Forsythia suspensa*, *Hibiscus syriacus*, *Prunus triloba*, and a host of others. I am surprised to hear that the common Hawthorn is not hardy at Salt Lake City, as we have several pretty trees of it here that bloomed profusely last spring. Hedges of Hawthorn, however, I have never seen in this country; the Osage Orange, the Hemlock Spruce, Arbor-vita, *Thuja orientalis*, Privet, and Norway Spruce are all used as hedge plants here.

WILLIAM FALCONER.

North Easton, Mass., U.S.A.

MARKET STRAWBERRIES.

STRAWBERRIES for market are grown everywhere round London, except, perhaps, in the Fulham Fields, the soil of which is too light for them; and, unless the ground is naturally suitable for Strawberries, it is found to be more profitable to devote it to other kinds of crops. A good sandy loam, rich and moderately moist, is considered to be best for them. The kinds grown now-a-days are great improvements on those formerly cultivated. They consist of British Queen, Myatt's Eliza, Mammoth, Eleanor, Keen's Seedling (one of the oldest and still one of the best), Old Pine, Dr. Hogg, Double Bearing, Elton, Kitley's Goliath, President, Sir J. Paxton, Sir Harry, Spring Grove, and a few others, the old Groend being still grown for preserving. As soon as the fruit is picked from a quarter of Strawberries, the best of the young runners are selected for forming a new plantation, and are at once separated from the parent plant; but, as a rule, not transplanted till September, or even till October, when the spaces between the rows of old plants are dug over in order that they may be cropped with Cabbage, Lettuces, or some other crop. The runners being then ready, they are planted on ground that had been trenched and well manured for a previous crop, but which is sometimes dug again and manured before the young plants are put in. The latter are set in rows 18 inches or 2 feet apart, and they stand 18 inches asunder in the rows; but in some cases 18 inches is the distance apart in all directions. In the latter case, after the first crop has been picked, every fourth row is lifted in order to make alleys, thus affording still more room; but the space is not lost, inasmuch as it is planted with Lettuces or Coleworts. Though Strawberries do best in open quarters, for the sake of economy they are sometimes set under trees and between fruit bushes in market gardens. After they have been planted they receive, and indeed they require, but little attention beyond keeping clean and mulching them. The mulching is applied early in spring, and consists of rough stable manure. Some spread it over plants and all, so as to screen the latter from cold in February and March, but in general it is put between the rows, where it gets bleached by the rains and afterwards forms a clean bed for the ripe fruit to rest upon. Dry weather is, if possible, chosen for gathering the fruit, which is put into punnets, that are again packed in large baskets, in which they are conveyed to market. As soon after the fruit is gathered as convenient, the alleys are dug and cropped. Strawberry plantations are allowed to stand for three years, when they are destroyed and fresh ones made. In private gardens, however, they might be allowed to stand for four years, and if well cared for, they will bear as heavy a crop of fine fruit the fourth year as the third. After that they should be destroyed and the ground trenched and manured for other crops. W.

A VALUABLE FRUIT REPORT.

WE gave a brief notice a few weeks since of the published report of the proceedings of the American Pomological Society at its last session at Boston. The great value of this report entitles it to additional notice. On looking over the volume, we are struck with the vast amount of pomological information contained in its 180 pages, and this information is the more valuable on account of being the latest intelligence, fresh from practical fruit raisers, not to be obtained from any other sources. Twenty-five years have elapsed since the organisation of the society, and, with the exception of a brief interval, its labours have, from the commencement, been directed by the wisdom and energy of President Wilder, and to his guidance and efficiency it is indebted for a large share of its success. The forty pages of the society's catalogue embrace an unequalled amount of facts in geographical pomology, in a most compact form, and for this the public is mainly indebted to Mr. Barry, chairman of the general fruit committee, and his able

associates. The thanks of the whole country are also due to the members of the society who have so largely contributed their observations and experience from all parts of the wide region embraced within its field of labours, from Nova Scotia to Texas, and from the Atlantic states to California and Oregon.

Apples.

The society's catalogue, or list of fruits, becomes increasingly valuable with each biennial revision and additions. It is the result of vast labour, and gives the results of reports in fifty different states, provinces, or territories, besides brief tabular descriptions. Of Apples, 260 varieties are reported. Of this number, seventy-three have only one vote or star each, being recommended by a single report or in a single state. Many of these appear to be quite local, while others are more or less known to cultivators; twenty-two have each two votes or stars; twenty-three have three votes; ten have four votes; twenty have five; nine have six; eight have seven; five have eight; eleven have nine; six have ten; twelve have eleven; two have twelve; five have thirteen; four have fourteen; five have fifteen; nine have sixteen; two have seventeen; two have eighteen; three have nineteen; four have twenty; two have twenty-one; one has twenty-two; four have twenty-three; one has twenty-four; one has twenty-eight; one twenty-nine, and one thirty-one. The inquiry will at once be made, what is the remarkable variety which has this pre-eminent vote of thirty-one states? It is the Red Astrachan, and what is remarkable, twelve of these are double stars, indicating the highest recommendation. This vote comes from the northern, southern, and western states, indicating the adaptation of this sort to nearly all regions. Yet amateurs regard it as hardly good enough to be classed with table fruit, its other qualities—hardiness, productiveness, handsome appearance, and reliability—standing strongly in its favour. Maiden's Blush and Early Harvest are nearly equal for their success in all regions, the former having twenty-eight stars, eight of them double; and the latter twenty-nine with nine double ones. Fall Pippin has twenty-four; Gravenstein, Early Strawberry, Sweet Bough, and American Summer Pearmain, each twenty-three; Summer Rose has twenty-two; Pirmate and Carolina Red June each have twenty-one; and Tallman Sweet, Famense, Porter, and Duchess of Oldenburgh have each twenty votes. It will be seen that only fourteen out of 260 are so fortunate as to get twenty votes or more from the fifty states or territories; and these fourteen are not always the best sorts for quality, but, their general commendation is owing to wide adaptation to different regions. The vote is not always a proof of value, such a fine sweet Apple, for instance, as Munson, does not get a solitary vote. But, usually, these stars are a fair approximate indication of merit.

The wide blank space, sparsely occupied with remarks in the report for 1871, is properly filled in this one with the tabular characters, and the few remarks are placed in small type at the bottom. These are attached to sixty varieties, leaving the remaining 200 without any. We do not quite understand the reason of the difference, nor can we quite agree with all that are given; as, for example, the only remark that is made on Tallman Sweet is, that it is "valued for stock feeding." We have known thousands of bushels raised, but never knew a single separate bushel of this sort specially employed for feeding stock. The same remark will apply partially to Golden Sweet and Jersey Sweet, to which the same remark is attached. Out of the whole 260, Ridge Pippin is the only one mentioned as "a long keeper." Bullock's Pippin is stated to be "valuable wherever known;" we have found it perfectly worthless from scab in New York. Autumnal Swaar is mentioned as "not showy;" on the contrary, it is with us a very smooth, fair, fine-looking Apple. We wish to avoid captiousness, but desire to assist a little in improving the catalogue, when we mention these few defects, and also the inappropriateness of the remark that the Onondaga is pre-eminently "the more esteemed the more known;" or the implied statement that the Madeleine is the only sort reported liable to blight, in the remarks "some say liable to blight," as if this, and no other sort, possessed this liability, and this only in the opinion of a few. The general perfection of the catalogue is, however, admirable.

It is interesting, in looking over the star marks, to observe the local high character attached to some varieties. Rhode Island Greening, for example, has double stars (the highest commendation), in most of the New England and middle states; but no stars in the west. Nearly the same is true of Roxbury Russet. The Baldwin is marked high in the New England and in some of the middle states; and in Ohio and Indiana, receiving sixteen votes, nine of them double stars. Ben Davis is nearly its counterpart at the West, receiving nineteen votes, and six of these are double stars.

Pears.

We well remember when the first pomological convention was held at New York (which subsequently became the American Pomological

Of the thirty-eight sorts of Cherries, Early Richmond, as a matter of course, receives the most extensive vote, being named in twenty-six states or territories, and double-starred in five of these, and ranging throughout the east and west, but not in the southern States, where Cherries generally fail. May Duke comes next, and receives twenty-two votes. Then follow Black Tartarian, with eighteen; Arch Duke and Belle de Choisy, with seventeen; Morello and Napoleon, each with sixteen; and Yellow Spanish and Black Eagle, each with fourteen votes. Of Currants, Red Dutch has twenty-two; Cherry, twenty-one; Versailles, twenty; White Dutch and White Grape, each eighteen; Victoria, fifteen; Black Naples, eleven; Red Grape and Fertile d'Angers, each eight; Fertile de Paluan, seven; Knight's Large Red, five; and Prince Albert, two. Houghton's is the most widely commended of Gooseberries. The Concord, among grapes, takes the lead for wide popularity, receiving stars in thirty-

Plan of the Catalogue.—The arrangement of the names of varieties in the catalogue is alphabetical, and according to the nomenclature adopted by the society. Synonyms are given in a few instances where it seemed necessary, and these are placed under the adopted names in italics. The columns are arranged thus:—In the first, the names of varieties; in the next seven columns the description, and in the remaining columns the states or districts. The state or district columns are not placed in alphabetical order, as in the octavo editions, but are grouped in divisions somewhat similar in climate, and other characters affecting fruit-culture. Thus: 1. Northern division—between 12° and 19°. 2. Central division—between 35° and 42°. 3. Southern division—between 28° and 35°. The state or district in which fruit is recommended for cultivation is designated by a star (*): and if the variety is of great superiority and value, two stars (**); if new, or recently introduced and promising, by a dagger (†).

NAMES.

[illegible]

* EXPLANATION OF ABBREVIATIONS.—The size is understood by l. for large; m. for medium; and s. for small. The form—r. c. for roundish conical; ob. for oblong; r. ob. for roundish oblate; fl. for flat or oblate; r. for roundish. The colour—y. r. for yellow and red; r. s. for red striped; g. y. for greenish yellow; rus. for russeted; y. rus. for yellow and russet. The quality—g. for good; v. g. for very good; b. for best. The use—F. fruit valuable for all family purposes; K. M. valuable for kitchen or market purposes; F. M. family and market. The season—S. for summer; E. A. for early autumn; L. A. for late autumn, and W. for winter. All these characters, of course, only designate leading positive features, and vary in their distinctness according to soil and climate in which they are grown. The origin is shown by Ros. for Russian; En. for English; Am. for American; Ger. for German; F. for foreign.

Peach and Nectarine Stones Splitting.—Can you tell me why many of our Peaches and Nectarines have stones which cut straight in two when the fruit is cut, the fruit being sound and of good flavour, growing in a house on a wall?—A. [Your correspondent's description of his Peach and Nectarine stones, which "cut straight in two when the fruit is cut," is not very clear, but I presume he refers to the stone splitting, which occurs occasionally in some Peaches, but most frequently in such varieties as the Noblesse Peach and the Victoria Nectarine, both strong-growing kinds, which favours the impression I have long entertained, that the disease is akin to gumming, and likely to yield to the same treatment. In affected Peaches the suture is generally deep; sometimes it is open, and the split stone visible, and gum is not unfrequently exuded from the wound. We have two vigorous trees here of the above varieties, growing in a strong loam, which have a few split fruit on them every year, but the disease never affects the crop to a serious extent. Your correspondent does not say what kinds are worst with him, nor to what extent the crop is affected. It would be instructive to learn this, and particulars about soil, &c. Meanwhile, we can only advise him to avoid maturing too highly; above all, to secure well-ripened wood for another year, and when thinning the crop after the fruit is stoned, to retain only the best developed and soundest looking fruit.

—J. S. W.]

On Grafting during Winter.

—To graft in December and January, when the sap is inert and in an absolute state of repose, appears at first sight to be paradoxical. In December, however, M. Flory grafted five wild stocks in clefts, and, after the operation, they certainly presented anything but a promising appearance. In the January following there happened to be some very severe frost; nevertheless, in March, the buds of these five grafts commenced to swell and became developed; while those of other grafts, which had been put on in the usual season, had scarcely shown any signs of vitality. The December grafts were completely successful, not one failure occurring out of the five. The following year a similar operation was performed at the same season, upon nearly 100 subjects, and this experiment was also attended with complete success. Indeed, cleft-grafting during winter is said to have been long practised in France, with the best possible results, for more than twenty years. In answer to the objection, that in the north, grafting during winter would not be successful, it is affirmed that it has been done out of doors in 7° and 8° of frost; and that in December M. Flory, after an extremely severe frost, grafted twenty-five black Cherries, and did not plant them until after the operation; and that, with the exception of one only, the experiment was perfectly successful. Should this practice be found worthy of general adoption, it will render cultivators some service, inasmuch as it will enable them to perform their grafting operations during the dead season, when time hangs heavily on their hands, leaving them at liberty to employ in some other manner the time usually devoted to grafting in the ordinary season.—*L'illustration Horticole.*

A Good Late Plum.—We have received from Mr. Dives, Wierton House, Maidstone, examples of an excellent late Plum, suitable either for kitchen use or for dessert. It is a chance seedling in the way of the Royal Dauphin, which is thought to be one of its parents, and will be found valuable, inasmuch as it is just in season when other sorts are getting over.

The Best Apples.—Being about to plant a small orchard, I shall take it as a great favour if you will kindly give me the names of the best Apples. A very small selection will suffice.—H. L. [*Winter Kitchen Apples:* Wellington, Winter Hawthornden, Alfriston, Brabant Bellefleur, Golden Noble, Northern Greening, Royal Russet, Gloria Mundi, Minchull Crab, and Blenheim Orange. *Dessert Winter Apples:* Cox's Orange Pippin, Bradlee's Nonpareil, Court-Pendu Plat, Cockle Pippin, Adams' Pearmain, Ribston Pippin, Sturmer Pippin and Lamb Abbey Pearmain. *Early Apples for Dessert or Kitchen:* Early Harvest, Keswick Codlin, Sugar-loaf Pippin, Wormsley Pippin, Cox's Pomona, Gravenstein, Emperor Alexander, Blenheim Orange, Lord Suffield, an improved Keswick Codlin.]

THE INDOOR GARDEN.

RICHARDS' CUT-LEAVED BEGONIA.

(BEGONIA RICHARDSONIANA.)

This pretty little species is a native of Natal, and was introduced to our gardens in 1871. In general habit and mode of flowering it bears considerable resemblance to the well-known *B. Dregei*, from which, however, it differs, in having lacinated foliage. It forms an elegant decorative plant and grows freely in a moderately cool greenhouse, forming bushy little specimens covered with multitudes of snow-white crystalline flowers. Like all the tuberous-rooted species of the genus, it is readily propagated by division, and if grown near the light, these divisions soon form flowering plants. A compost of turfy loam, leaf mould, and coarse sand suits it admirably, and, like most other members of the genus, it requires an abundant supply of root-moisture when growing. Plants of this desirable little species have already found their way into Covent Garden Market, and it well deserves cultivation as one of the prettiest plants in the whole group. It was obtained from South Africa by Mr. James Richards, in complement to whom it is named. B.

Richards's Cut-leaved Begonia (*B. richardsoniana*).

POINSETTIA PULCHERRIMA.

How differently do we find this plant treated by different cultivators; under some it has a bare stem of old wood from 1 to 2 feet long, a height to which it is cut back year after year, and the young wood that is annually made, is by no means vigorous or healthy; some, again, allow their Poinsettias to remain in the stove all summer, thinking they are right in so doing; but, like many other plants, Poinsettias succeed best when they are not kept in stove-heat in the summer time. I prefer dwarf plants that have been allowed to rest a short time before being re-potted or cut back. They should not be pruned and re-potted at the same time, as that would prove too great a check to them. A better way is to cut them back two or three weeks before they are re-potted, as is done in the case of Pelargoniums; when they push afresh they may be re-potted, and, if what they are growing in, was nearly all fresh good soil last season, perhaps, it may not need much disturbance. Sometimes Poinsettias make quantities of coarse roots, and, when that happens, it is generally best to remove most of them, preserving such as are small and fibrous. Plenty of drainage is necessary for all plants, but especially so, for such as are expected to do good service during winter. As to soil, about one-half loam, and one-half turfy peat, with plenty of sand to keep all open and porous, will answer perfectly. After the plants have been cut back three weeks or so, and have been re-potted with care, they may be placed in a little bottom-heat in order to start their roots into growth, and likewise to assist the buds to push more freely; a fortnight or so will be quite long enough to keep them upon bottom-heat. By turning one or more plants out of their pots, it will be seen whether or not the roots have reached the sides of the pot, and if so, keep them cooler or remove them to a cold pit, where they can be kept shut up closely for a time, and when they seem inclined to grow, give them more air, and, perhaps, they may require shading during bright sunny days for four or five hours; but, be sure to keep them well supplied with water, and the bottom of the pit should always be damp, at least, while they are in a growing state. They will often push from three to five new branches from 18 inches to 2 feet 6 inches in length, and become well furnished with large and healthy leaves, which form a nice ground-work on which to show off

their brilliant bracts during winter. After a few years' attention in this way, they will, of course, increase sufficiently to require a good-sized pot, i.e., if good foliage and handsome plants are desired. Poinsettias will succeed without artificial heat until well advanced into October, when they should be removed to their winter quarters.

Barnet.

G. DAWSON.

LESCHENAULTIA FORMOSA.

SOME twenty years ago this occupied a prominent place on our exhibition tables; but now, somehow or other, such a distinction is seldom conferred on it. It is too good a plant to be lost sight of, more especially as its culture is so simple, that it may be successfully grown in any greenhouse where plenty of light is admitted. The kind of soil most suitable for it is two-thirds of rough turfy peat, and one-third of silver-sand, adding to this one-sixth of the whole of light, mellow, fibry loam. Let these be well mixed together, and used in a perfectly coarse lumpy state. Procure young healthy plants in March, and, supposing them to be in 48-sized pots, in which they have been wintered, they may be at once shifted into 24's, taking special care, however, that the pots are perfectly drained with broken potsherds to the depth of about an inch, having a little chopped Moss sprinkled over the drainage, to prevent the soil from mixing with the latter, and thereby obstructing the free circulation of water—a most important point in the cultivation of this plant. After the operation of potting is performed, let the whole be well watered through the rose of the watering-pot, and then placed in a light part of the greenhouse near the glass. With attention and good management it will have made, by the middle of July, sufficient progress to require another shift. It may then be moved into a larger pot, following precisely the same mode as in the spring shifting. It will then remain in this pot until the following March, when it will be ready for a final shift, say into a No. 12, in which, during the following summer, it will become an object of surprising beauty—an ample recompense for the care and attention bestowed upon it. The training of the plant, during its growth, should not be forgotten. One stake alone will be sufficient for this plant; this will take the centre or leading shoot, and the lateral branches may be, as occasion requires, supported by ligatures of green worsted. The form, in this case, will be a perfect cone, the under branches hanging down over the sides of the pot; surely such a form and arrangement are decidedly superior to torturing and twisting the branches in every direction, as is often done when wire and stakes are used. No plant with which I am acquainted is so apt to suffer from continued profuse blooming than this. Therefore, in order to strengthen its growth and add fresh vigour to its constitution, the flowers should be occasionally entirely and carefully picked off. It has been recommended in the culture of this species to place it in heat, but on no account do this; Leschenaultias are thorough greenhouse plants, and must be treated as such. Plants of that kind, when exposed to high temperatures, in an atmosphere charged with vapour, acquire an artificial constitution, and assume a weakly attenuated appearance, quite unnatural to a plant of temperate habits. This is the common cause of inexplicable premature dissolution. Leschenaultia requires, and should have, a quiet, cool temperature, with plenty of light, and a regular yet judicious supply of water. Plants treated in this manner will never suffer to the same extent by the heats of summer or the damps of winter, as those produced in warm houses. In the autumn it may be placed in the open air, in a partially shady situation, which will harden its wood, and the better enable it to withstand the long confinement to which it must be subjected during winter.

R. G.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Trailing Plants on Orchard-house Walls: H. The best are *Lapageria rosea*, Ten Roses, *Berberidopsis corallina*, *Camellias*, *Plumbago capensis*, *Fuchsias* (planted out of course), *Heliotropes*, *Bignonia Cherere* (if the house be a large one), and *B. jasminoides*.

Grafting Epiphyllums: E. B. Head down your *Pereskia* stocks to the height required—12 or 14 inches, and making a slit in the top, insert your graft, an ordinary shoot (it may be 2 or 3 inches in length), and bind together with a small piece of matting. Place the plants so worked in a close, warm frame, and in the course of ten or twelve days they will have united.

Bougainvillea Culture: E. B. The chief point is the ripening of the young wood, and this is generally effected by growing the plants in a warm sunny house, and by not having their roots in a too moist medium. Close pruning, which is conducive to the development of strong sappy growth, is to be avoided; and the branches should have scope to grow.

Ophiopogon Jaburan aureo-variegatum.—A handsome variegated plant, with broad Grass-like leaves, either wholly golden-yellow, or broadly margined with that colour. The plant is very pretty in the normal state of green foliage, with its numerous spikes of violet or purple-blue flowers, resembling the well-known Grape Hyacinth in shape; but the contrast between the flowers and yellow foliage is very effective. It is an excellent pot-plant, and suitable for room-decoration when cultivated in pots in the greenhouse, whether in flower or not, the handsome form of the arching grassy foliage being very pleasing. *Ophiopogon spicatum argenteum* is a smaller-growing sort than the last; but also very pretty, particularly as a pot-plant.—*Gardener*.

THE GARDENS OF ENGLAND.

BRANTINGHAM THORPE.

By J. C. NIVEN, Botanic Gardens, Hull.

ON a spur of the chalk hills, that may be said to originate at Flamborough Head and terminate in the Dover cliffs, is situated the charming residence of Christopher Sykes, Esq., M.P. for the East Riding of Yorkshire. What it lacks in palatial dignity is amply compensated by the lovely surroundings, which combine a fair share of Nature and Art, with a predominance of the former above the latter. The entrance to the park is about a mile from Brough station on the North-Eastern line, flanked by a lodge, recently erected in the Elizabethan style; it is neat, but by no means pretentious, and admirably in keeping with the hall itself. The drive is through a nicely undulated piece of park scenery, with a considerable slope from north-east to south-west; as it gradually rises, the charming view of the river and of the Lincolnshire coast expands, till, when you reach the terrace on which the house stands, you command a lovely panoramic view of the glorious estuary of the sea, known as the river Humber, but, seeing that it is here fully three miles wide, and viewed from the terrace lengthwise for a distance of at least twelve miles, through which it retains the same width, at that point branching into the Trent and the Ouse right and left, it realises, with the foreground beautifully broken by the groups of trees in the park, the idea of a lake of almost unlimited extent. There is, indeed, no site of such commanding beauty, so far I have seen, in the East Riding. The hall stands at an elevation of some 200 feet or more above the level of the river, and the hills rise above it to a similar height, clothed with massive plantations, broken every here and there with ordinary fields, which, in some cases, lose themselves over the crown of the hills, thus giving distance and variety to the landscape. The hall, as I said before, is unpretentious, and has recently undergone considerable alterations; but, so perfectly in keeping is the new work with the old, that it is almost impossible to tell one from the other. It is Elizabethan in style, built of rubble stone-work, and pretty well suffused with Ivy, Banksian and other Roses, Wistaria, and, though last not least, *Ampelopsis Veitchii*, lovely in its growth, and still more lovely in the intense crimson colour which it assumes in the autumn, and carries for double the time that the old Virginian Creeper does; without this garniture the house would have a bald appearance, but with it, a beauty of detail far greater than could be attained by the stonemason's and sculptor's art is found at the hand of Nature, and the decorations may thus be said to be drawn from the primitive, but at the same time, purest source. Fronting the hall is a terrace, about 50 feet wide, chiefly of gravel and Grass. This is bounded by a low parapet-wall, and enlivened by a few vases, giving just a sufficiency of colour to light up the fore-ground. This wall is to be substituted by a balustrading, and to be extended to a greater distance from the house, which will be a great improvement; in fact, considerable alterations are contemplated, by which the pleasure grounds will be extended, so as to take in two *Wellingtonias* planted on a knoll at the south-east end of a house. These trees are interesting, as *souvenirs* of a Royal visit, having been planted by their Royal Highnesses the Prince and Princess of Wales. They are now about 12 feet high, and show every prospect of making noble ornamental trees. The ground rises rapidly towards the back of the hall, by a terrace slope of some 10 feet in height, reached by a flight of steps, and on this higher level is the flower garden. Its position at the back of the house, on or above the level of the top of the lower rooms, is undoubtedly somewhat anomalous; but, seeing that the view of the house is well shut out by means of Yews and large evergreens, and that formality is almost entirely absent in the arrangement of the flower beds, and that the surface of the ground is disposed somewhat as Nature left it, or, at least, looks so, which is the highest compliment I can pay to the artist who formed it, the surprise, on reaching the top of the high flight of steps from the lower terrace, is as great as it is unexpected. The flower garden here is by no means extensive. There are no long lines of floral ribbands, one of the most expensive and wasteful forms of flower gardening there is. The impression they convey is instant-

neous; but, as you progress onward, no new beauty or form strikes the eye. Here the flower beds are distributed on the uneven, but gracefully-rounded, surface, tolerably wide apart; and the shape of each bed, or each group of beds, is adapted to the surface. In arranging the planting, each flower bed or group of beds, is complete in itself, and each one possesses its own individuality of character—a grand point, which, with taste and discrimination, may be carried out without any interference with the several beds—in other words, without interfering with the unity of the whole, as seen from a distance. This is a grand point in flower gardening, not only to satisfy the eye, but to supply an unlimited amount of interest in regard to the various materials that are called into play to work out the details. It would be difficult to particularise the component parts of such a flower garden; nevertheless, having stated what I have, I am bound to give one or two illustrations. Nothing could be more lovely than a Maltese cross, consisting of an edging, about 8 inches wide, coming up to the very margin of the Grass, of the silvery *Antennaria sericea*, often called *toментosa*, the centre part being filled with a mass of *Lobelia Blue King*—a variety of compact uniform growth, not tufty, and possessing a soft light blue colour. The silver-grey and the delicate azure combined are charming, and would form a fitting setting for such a glorious ruby-flowered *Pelargonium* as the new one known by the name of *Heart's-ease*, which I saw in one of the plant-houses at Brantingham for the first time. Another narrow bed was margined with *Sempervivum calcareum*, generally stiff and formal, but, in this case, beautifully contrasted with a nice belt of *Leucophyta Brownii*. This I was delighted to see, as it fully bore out a prognostication I made in your columns some two years ago—that it promised to be a very model of a bedding plant; and here it is, its tiny branches clothed with the purest frosted silver coating, rising perpendicularly from the surface, devoid of all stiffness and formality. In the centre of the narrow bed rose some of the newest of the Silver-leaved *Geraniums*, here a lovely rose, there an intense scarlet, interspersed with various *Lantanas*, which latter, by the way, will prove, in dry seasons and dry situations, valuable and lovely bedding plants. The chief beauty of this bed hinged on the peculiar growth of the *Leucophyta*. A circle of considerable size planted with Silver-leaved *Geraniums*, consisting of *Princess Alexandra*, *Bright Star*, and *Snowdrop*, interspersed with the *Blue Violet*, magnificent, whose flowers just rose sufficiently high to intermingle with the silvery foliage, was exceedingly effective; it was margined with *Golden Chain*, minus its flowers, and centred with a group of the graceful *Humea elegans*. On a tolerably steep sloping bank, rising to the foot of an irregularly outlined shrubbery, are two carpet beds, shaped in the form of an elongated letter S. These were so lovely and distinctive, that, at the risk of being tedious, I must endeavour to give your readers a brief description. Externally they are margined with a double row of *Sempervivums* in one case, and *Echeverias* in the other, placed closely together. Five figures are picked out in the same manner, along the centre line of each bed, by means of *Sempervivums*; each figure having a distinct species as its frame work, and in each a good bold plant, of the larger growing succulent plants, finds a fitting home, expanding their massive leaves over a carpet of some of the smaller growing *Houseleeks* and *Sedums*, interspersed with seedling *Portulacas*, whose gorgeous blooms, on a bright sunny day, add such a charm as they only can give. External to these patterns is a mass of *Alternantheras*, consisting of *paronychioides*, with its major variety and *amabilis*, as dense and dwarf and fresh in colour as can be, although a cold night or two a few days before my visit had completely destroyed the beauty of the *Coleus*. A series of little circles, again margined with *Sempervivums*, contained in the centre a plant of the thick-leaved *Pachyphytum*, the whole completed by a golden carpet of the now popular *Stellaria graminea aurea* neatly defined by the formal margin along the outside of the bed, and loosing itself with charming irregularity beneath the parti-coloured foliage of the *Alternanthera*. This plant is a most invaluable substitute for the *Pyrethrum*, requiring, as it does, no training, and gaining much in its irregular elegance of outline as compared with the formality of the *Golden Feverfew*. One item I forgot to mention was, that above the golden carpet was

dotted at regular distances the Double *Lobelia*; as yet, it has not been very effective, owing to the plants being very small when planted out, but another week of autumn sunshine will see each tuft one mass of lovely blue, and then these carpet beds will be little, if at all, short of perfection. The reader will note that situated as they are on a sloping bank, they can be seen at a distance, without the necessity of standing over them, and further, that such conditions are admirably adapted for the growth of such plants as they contain.

Amongst the newer *Geraniums*, I especially noted three bronzes, viz., *Marshal MacMahon*, *Emperor of Brazil*, and *Black Douglas*; not only were they distinct and well defined in their markings, but also of vigorous constitution. Amongst yellow leaved, *Robert Fish* and *Yellow Boy* are two excellent sorts, the former being the dwarfest and freest bloomer. Among the silvers, *Turner's Bright Star*, *Sibyl*, *Princess Alexandra*, and *Silver Gem* have all stood the test up to the present time, and are considered by Mr. Kingston as best adapted for the locality, as also are *Flambeau* and *Lady Cullum*, from the host of tricolors. One word of commendation I must give to *Brilliantissimum*, admirably dwarf, intensely scarlet, and producing its flowers in greater abundance than any other scarlet; it is not half as frequently seen as it ought to be. The most important knoll in the flower garden is crowned by a sort of quatrefoil-shaped conservatory, consisting of high pilastered, upright sides, and a curvilinear iron roof, whose narrow spaces between the sash-bars, at once indicate that it is no modern structure, but, very possibly, one of the oldest iron conservatories in the East Riding. In the central portion is a fine collection of noble *Azaleas* and *Camellias*, the eastern wing being devoted to hard-wooded greenhouse plants, and the western to *Heaths*; on the north side of the stages, shaded, of course, from the direct sun, but exposed to a full current of air, are cultivated fine plants of *Nothochlœnas*, *Cheilanthes*, and other *Ferns*, in fine vigorous health, and of sturdy aspect, contrasting wonderfully with the sickly appearance they present when growing in a hot moist atmosphere. The very native habitats of this charming section point at once to dryness as an essential element in their successful culture, and Mr. Kingston's mode of treatment clearly shows that coolness has an equal value as a concomitant. I may add, that many of these plants have been grown for years under the same conditions. On the high ground, north of the conservatory, are some nice specimens of *Conifera*; amongst others, *Taxodium sempervirens*, fully 32 feet high, its lower branches sweeping the trim turf with a beautiful irregularity of outline, to an extent of 30 feet in diameter. The circumference of its stem at 3 feet from the ground is 5 feet 6 inches; here I may add that this tree, so liable to turn brown and wither in foliage during winter, remains true to its specific title, and is always green. No doubt the happy adaptation of the *Taxodium* to this locality induced the selection of two of its giant brethren, the *Wellingtonias*, as the commemorative trees, before alluded to. I noticed also a remarkably fine specimen of *Cryptomeria*, about 25 feet high and 20 feet in the diameter of its branches, densely feathered to the ground.

Divided from the flower garden by a fine bank of regularly trained common *Laurel* and reached by means of a steep serpentine walk, is the kitchen garden, about $1\frac{1}{2}$ acre in extent. As usual, the north wall is devoted to a range of *Peach-houses* and *Vineries*, with a peculiarity in their structure one does not often meet with, in the fact that the whole range slopes fully 4 feet from east to west, thus adapting itself to the general slope of the ground; nor, I am bound to say, is the effect at all displeasing, as some of my readers might imagine. The *Peach* culture is admirable, but the *Vines*, as a rule, lack that vigour of constitution that one might expect them to attain, with a fine dry chalky sub-soil. I would note in passing, that I met with a *Vine* in cultivation that I never came across elsewhere, called the *Prince de Hérault*; its berries have a powerfully aromatic Strawberry flavour that is highly esteemed on the dessert-table. They, as well as the bunches are both small, and the latter somewhat ragged; but its peculiar aroma alone renders one plant of it, at least, well worth cultivation. Outside, and eastward of the kitchen garden, is a span-roofed *Orchid-house*, almost buried in the ground, where *Orchids* and *Pitcher* plants, as well as a choice selection of

Ferns and Lycopods, indicate, in their perfect vigour, the admirable adaptability of such a house as compared with a lofty one; the walls, on all sides, are continuously giving off both moisture and heat, two essentials that ought, by every possibility, to be retained within such a building. Close by there is a series of handy pits, half-span, well heated and ventilated, in which the growth of various winter-flowering plants is admirably carried on; this is a part of the establishment that is brought largely into requisition, table decorations, hand-bouquets, and button-holes of the most *recherché* description being sent up to London daily during the season. I omitted to mention that in the Orchid-house the *Oncivandra* or Lattice-leaved Plant, was growing vigorously, producing hundreds of finely-developed leaves. I ought also to specialise two creepers, viz., old *Jasminum sambac* and *J. dianthifolium*, two of the most fragrant plants grown; and that the roof was studded with scores of the large golden blossoms of the *Allamanda Hendersoni*.

Although my remarks have already extended to too great a length, I must not omit to state that a fine south border outside the kitchen garden, in a position nicely sheltered from the wind, is devoted to the culture of a choice collection, or rather selection, of herbaceous plants. Miss Sykes takes almost as deep an interest in these plants as does Miss Hope, of Wardie Lodge; she thoroughly appreciates the continuous variety that such a border offers. The excessively dry summer we have passed through, added to the natural dryness of the locality, has left some vacancies; these, however, will soon be filled up. I will only supplement the foregoing description of Brantingham Thorpe, by stating that the neatness, order, and system which is evident through the entire management of the place, reflect the greatest credit on Mr. Kingston, who has for years ably filled the office of gardener, and now holds along therewith that of steward of the whole estate.

Parks and Open Spaces.—The following is the acreage of the parks, commons, and other open spaces, under the charge of the Metropolitan Board of Works:—

	ACRES		ACRES
Finsbury Park	115	South Mill Field	28
Southwark Park	63	Clapton Common	93
Blackheath	267	Stoke Newington Common . .	53
Hampstead Heath	210	Waste Lands at Dalston	
Shepherd's Bush Common . .	8	Lane, and Grove Street,	
London Fields	27	Hackney	1
Hackney Downs	50	Tooting Beck Common	114
Well Street Common	30		
North Mill Field	29		1,916

Promotion of Germination by Camphor-Water.—A series of experiments, undertaken by Professor Vogel, of Munich, to substantiate the fact that camphor-water promotes the growth and prevents the wilting of Tulips, &c., led to the discovery that old seeds, which have almost lost the power of germination, not only recover it when treated with camphor-water, but even germinate in larger numbers and more rapidly than fresh seeds under ordinary conditions. Thus Beans, that required eight or ten days for germination under ordinary conditions, develop in camphor-water after three days; and Cucumber seed that would not germinate at all in good soil, germinated soon, and without a single failure, in camphor-water; and what is more remarkable still, the seeds so germinated manifest a continued effect of the camphor, when transferred to good garden-soil, in the vigour of growth and freshness of the plants. This fact, it is suggested, might be of service, especially in cases of expensive seeds, that germinate with difficulty.

The Storage of Rain-water.—Some calculations published in the *Sanitary Record* show that owing to deficient means of storing water, we, in this country, make use of only a seventy-fourth part of the actual rainfall. The area of England and Wales, being taken as comprising 37,000,000 of acres, and reckoning that about 32 inches of rainfall during each year upon an average, and each inch of rain falling upon an acre of ground supplies 22,622 gallons, it will be seen that this portion of the United Kingdom is yearly supplied with over 27,000,000 gallons of water, in the shape of rain, not including dew-fall, which is often very abundant. It is calculated that an ordinary cottage roof covering 2½ poles, can collect some 7,000 gallons, taking the rainfall at 20 inches only, while a large farmhouse and out-buildings, covering 10 poles, will collect over 28,000 gallons yearly, all which supply might be received in tanks, which could be constructed at a trifling expense to each village, if the inhabitants combined to defray it.

THE FLOWER GARDEN.

NOTES ON THE NEW LOBELIAS OF 1874.

HAVING promised you some account at the termination of the summer bedding season of the respective merits of the ten varieties of new *Lobelia*, I have had under my notice in my trial border during the summer, I shall now proceed to consider them seriatim. The four varieties sent to me by Messrs. Henderson, of Wellington Nurseries, St. John's Wood, were named—(1.) White Brilliant, but scarcely, I think, deserving this name, as it is apt to show blue streaks at times, and, though of a compact upright growing habit, produces but medium-sized individual pips, and is not to be compared for purity of white or size of flower with Dixon's *Nivea*, which still holds its place (in my opinion, at least) as by far the best and most distinct white in cultivation. (2.) *Speciosa bicolor*; this is by far the prettiest of Messrs. Henderson's set, as far as size of individual bloom and distinct marking and division of the two colours are concerned, but its habit of growth is, unfortunately, weak and slow, at all events in a dry summer, which made it fail to cover the circle of ground allotted to it, and so produce but little good effect; it may be more satisfactory in a moister season, and, as the individual flowers are so good, I shall try it next year. (3.) *Pumila maxima azurea*; this variety has little, if anything, to recommend it for cultivation except its compact habit, as its blossoms are not produced very profusely, and are, individually, inconspicuous either for colour or size, being but little larger than those of the old *pumila grandiflora*, and by no means of a bright blue. (4.) *Porcelain Brilliant*; neither has this variety much to recommend it beyond its habit, which is upright and tufty, but the shade of colour is not bright, and the individual flowers are small. Of the three varieties sent out by Messrs. Carter, of Holborn, under the names of Faith, Hope, and Charity, the second alone is valuable, being of good, low-growing, compact habit of growth, and producing good large flowers of a clearly marked pure white and bright blue very conspicuous and a most marked improvement on the old variety. The other two are utterly and absolutely worthless; the one being a dull, pale, reddish-brown, with very small flowers, and the other sporting all sorts of flowers, no two of the six plants under notice producing blooms alike. Of the three varieties sent me by Messrs. Dixon, of the Amhurst Nurseries, Hackney, Painted Lady is by far the best and most valuable, as, though rather of a straggling habit of growth, it continues to produce its very prettily striped blooms up to the very end of the season, and long after the beauty of all the other varieties in the border has come to an end, being now, as I write (Sept. 14), still covered with fresh and beautiful blooms, and seeming likely to continue to produce them till cut off by frost. *Purpurea* is a variety of little individual merit, though good for massing, being a strong compact-grower with a deep (though dull) shade of blue. *Carulea* has considerably disappointed me, as, owing perhaps to the very dry season, it made very little growth, and produced so few flowers as to be in nowise effective, though, from its shade of colour, being by far the lightest of any I have yet seen, it may be useful in a moister season. Henderson's beautiful variety of '73 *Mazarine Gem*, was much admired here this season, as it is quite unequalled in depth and brilliancy of colour, and, owing perhaps to the dry season, did not straggle and spread about by any means so much as the first year I had it; planted inside a row of the *Stellaria graminea aurea*, or Golden Chickweed, it proved a most beautiful and effective contrast along the whole of the front of the trial border, and in a double row in a scroll bed with a row of that finest of bronze-bicolor *Geraniums*, Marshal MacMahon, up the centre, it was exceedingly admired. The double *Lobelia*, though it may be forced into flowering by keeping it starved in pots and plunging these in the border, can, after all, be considered but of little or no value for bedding purposes, as it lasts but a very short time in flower, and if not allowed to grow into a large green tuft of foliage, seems to resent the confinement of its roots, and take refuge in dying. Dixon's white *Lobelia nivea*, is still far the best white in cultivation, and, if a little more compact in habit of growth, would, I think, be perfect. The same firm

has, however, another new white to be sent out shortly, and to be named, I believe, *Nivosa*, which is said to be even of a purer white, and to have a larger and more conspicuous pip than even *Nivea*.

W. E. G.

THE COTTAGE IN KENSINGTON GARDENS.

THE little flower plot in front of the cottage in Kensington Gardens is just now an object of considerable interest on account of the glimpses of rich colour afforded by the bedding plants which it contains, indeed, few other spots in the gardens are better fitted for showing off glowing colours than this little semi-circular enclosure, backed up as it is by a somewhat formal looking castellated cottage, made beautiful by the dense growth of fresh glossy-leaved Ivy, under which it is more than

fully a month, or even six weeks, after the beauty of *Pelargoniums*, *Calceolarias*, *Verbenas*, and most other flowering plants, is over, or, at least, greatly impaired. The use of crimson or carmine *Alternantheras* (which are everywhere in beautiful condition), *Golden Peverfews*, *Mesembryanthemums*, *Golden Chickweed*, *Echeverias*, and silvery *Kleinias*, *Santolina*, and *Centaureas*, in addition to their being more permanent, also afford much more harmonious masses of colouring than can be obtained by the use of ordinary bedding plants. In the semicircular bed just mentioned, the prevailing tints are blue, carmine, and soft golden-yellow; and, when seen in reflected sunlight, these colours forcibly bring to mind the rich flood of light sometimes seen issuing through a richly painted window; and this, viewed against a cool carpet of turf, and in a cosy nook, associated by noble trees, forms a pleasant little

The Cottage in Kensington Gardens.

half-concealed. This somewhat sombre looking back-ground contrasts well with the lighter coloured drapery afforded by the Chestnuts, Limes, Oaks, Planes, and other forest trees by which it is in part surrounded, while the fresh greenness of the turf forms a pleasing middle tint, that sets off the display of glowing colour to much advantage. Although, as will be seen on reference to our plan (see page 301), this is strictly a geometrical arrangement, yet much of the consequent formality is obviated by the judicious employment of isolated specimens and effective little tufts of Palms, Cycads, *Dracenas*, and other plants of elegant habit, which supply beauty of form, and stand out in pleasing relief amid the bright masses of colour. The large semi-circular or panelled bed seen on the plan also affords an excellent illustration of the value of dwarf foliage plants for ensuring late autumnal effects, as by their use we secure bright colour

picture well worth reproduction in our pages. It need only be added that, although some 10,000 plants are employed in this arrangement, the result, as a matter of special display, amply repays all trouble connected with their management, and this little garden annually attracts thousands of admiring spectators during the summer months.

F. W. B.

EARLY TULIPS FOR SPRING BEDS.

TULIPS must be grown in a rich soil to succeed well in beds. It is a mistake to plant them in poor exhausted soils or beds that have had all the heart taken out of them by *Pelargoniums*, or some other gross-growing plant, leaving nothing for the Tulips to feed upon. Before Tulips can be planted in such beds they should be forked or dug over, and the soil well beaten to pieces; they should then be opened to the depth of 6 or 8 inches, and given a good dressing of

thoroughly decayed manure, from an old Melon frame, and leaf-soil. On this, place about 4 inches of soil and fork all well together, removing the remainder unless required to raise the bed. As a rule, bulbs for outdoor decoration are not planted till the last week in October or early in November. Beds planted solely with Tulips are disappointing, notwithstanding their brilliancy and effectiveness for a time. The aim should be to gain prolonged effects, or, in other words, a succession of floral beauty; and to secure this something should be used in combination with Tulips. Aubrietias, such as Campbelli, græca, and purpurea, with their lavender, lilac, and violet flowers, are well adapted for forming edges to large Tulip beds, and entirely carpeting small ones. Take, for instance, a bed of A. Campbelli, perhaps one of the best for general spring work, and about it dot little clumps of the crimson-flowered variegated double Daisy. Let us suppose that previously to planting the bed there had been placed in it a few pure white and scarlet-flaked Tulips; all would be in bloom about the same time, and the effect would be pleasing in the extreme. Then there are the double Daisies, now a somewhat numerous section, and invaluable in small gardens. There are the white, the pink, the mottled-crimson, the deep crimson, and the pretty variegated-leaved one. Daisies, when planted in a good rich free loamy soil, form a dense carpet or undergrowth, and flower with great profusion and continuously. A wonderful spring garden might be made up of Daisies and Aubrietias alone. The earliest to flower is, unquestionably, the mottled-crimson, the others coming into bloom soon after. Cheiranthus alpinus, too, a most effective dwarf-growing yellow perennial Wallflower, must not be forgotten, nor the orange-coloured C. Marshalli, both a little late, but scarcely rivalled for decorative effect. The white Arabis alba, and the variegated-leaved one; also Myosotis dissitiflora the largest and earliest of the spring-flowering Forget-me-nots; the pretty prostrate Phlox frondosa and P. Nelseni, the former with rose-pink, the latter with white flowers; the double white Saxifraga granulata flore pleno, Silene pendula, with rose-coloured flowers, and also its white variety—these, and others of a similar character, may be used in combination with Tulips, and with happy effect. Let it be remembered, too, that all the foregoing are hardy plants that may be readily increased by root-division, or raised from seeds sown at the end of summer. As to Tulips, the following can be recommended with confidence, viz., Belle Alliance, brilliant scarlet, dwarf and fine; Canary Bird, clear rich yellow; Purple Crown, rich dark crimson; Scarlet Van Thol, glowing scarlet; Keizer Kroon, crimson-scarlet, edged with clear yellow (a magnificent variety); Le Matelas, white, flushed with bright rose; Paul Morelce, cerise crimson, distinct and fine; Queen of Violets, pale violet, very fine; La Pluie d'Or, clear yellow; Proserpine, rich dark rose; Rosa Mundi, white shaded with rose; Royal Standard, white feathered with rosy-crimson; Thomas Moore, orange; and Van der Neer, purplish-violet. Let it be borne in mind also that when once obtained, a collection of varieties of these early Tulips may be made to last for years. All that is required is a piece of light ground, to which the Tulips can be transferred when they are lifted from the beds, keeping each variety separately, and allowing them to ripen their foliage and mature their growth. A compost consisting of sandy loam and leaf mould should be placed about the roots, which will repay a little care of this kind. Q'uo.

FANCY POLYANTHUSES FOR OUTDOOR SPRING DECORATION.

No more useful plants exist than what have been termed, for convenience sake, fancy Polyanthus. They need some such separate designation to distinguish them from the gold-laced varieties of our florists. Originally of German origin, certain flowers were chosen because of their large size and brilliancy of colours, and these have now been selected and bred from so carefully as to have brought into cultivation a strain that far surpasses, for decorative effect, anything of the kind hitherto used in our winter and spring gardens. Of vigorous habit of growth, these Polyanthus throw up large trusses of flowers of great beauty. None of the delicacy of constitution which belongs to the gold-laced Polyanthus of the florist, and which results from so much inter-breeding in order to get quality, belongs to this new strain; their vigour appears to set at defiance all the exigencies of weather—severe cold and extreme wet alike do them but little apparent injury. Some of these Polyanthus having been shown in public at the meetings of the Royal Horticultural Society during the past spring, and having excited a good deal of interest, it is not surprising that a batch of them should be named for distribution; and so unmistakably fine were some of these as to receive first-class certificates. One of the most striking is termed the Bride. This has large pure white flowers, with a deep orange centre, borne in a bold massive truss on a stiff foot-stalk; and

is suitable either for beds or pot-culture. A pure white Polyanthus cannot fail to be an attraction, especially when it possesses high-class quality like that seen in the variety under notice. Pure too, as it is in colour, it has stood exposure to all weathers in the open air with but little perceptible injury. Another is named Viceroy; this has bright sulphur-coloured flowers, with a deep orange centre, very fine pip, and splendid truss; I have seen this very fine indeed, both in pots, and in the open ground. Jessie is distinguished by its bright rosy-violet hue and striking yellow centre, which is regularly and handsomely marked with orange; large pip, bold truss, very free, fine, and showy. Etna, as its name implies, is a bright and effective variety; the colour magenta-crimson, with a slight spot of white at the extremity of each segment, and a bold and striking golden centre. This variety is of a colour that stands exposure well. Field Marshal is a very fine variety, with rich velvety crimson flowers, distinctly margined with white, and a golden centre with reddish-orange rays; pip and truss alike are fine and bold. The last is Warrior: this has rich shaded magenta flowers, with a yellow centre rayed with deep orange, fine bold pip, and truss showy and striking. These new forms of Polyanthus may either be cultivated in pots or in the open ground. If grown in pots, they should be potted in a good free loamy soil, with which is mingled some decayed manure that will readily crumble to pieces in the hand, and some leaf soil. When potted, they should be put in a cold frame or cool greenhouse, but allowed a free circulation of air, or the plants will become infested with green fly, which will impair their growth. A cold frame is best, as by tilting the light air circulates freely among the plants, and green fly will not be so troublesome. Just before the plants come into flower, some of the surface soil should be removed and replaced with other material of a rich character. If planted in beds in the open ground, the soil, which should be of a loamy character, should be well stirred to the depth of a foot, and some rotten manure and decayed leaves well forked into it. All Polyanthus require depth in which to root, and what is known as a cool bottom, such as sand or clay. The roots strike down deeply, and by doing this the plants are enabled to hold their own even during continuous dry weather. In addition the plants also form fresh roots just beneath the leaves; hence, the necessity for top-dressing, which should consist of dung, well-decayed, leaf mould, and stiff loam mixed together, this should be applied just when the plants are throwing up their flower-stalks. Should the weather be dry and hot in April, as is sometimes the case, water should be freely administered. R. D.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Hardy Annuals for Flowering Beneath Standard Roses.—I wish to know the best annuals to sow or plant in Rose circles at the end of this month. They should be hardy enough to stand the winter on a dry soil.—A. [Sweet Alyssum, Limnanthes Douglasii, Leptosiphon densiflorus, roses, and luteus; Nemophilas, Collinsia grandiflora, verna, and bicolor; Silene pendula, S. Armeria, Eschscholtzia crocea, Godetia tenella, viminea; Saponaria calabrica, Hymenoxys californica, Ionopsisidium acule, and Gilia tricolor.]

Weeds on Walks.—The following method of destroying weeds on walks is pursued at the Mint in Paris, with good effect:—Ten gallons water, 20 lbs. quicklime, and 2 lbs. flowers of sulphur are boiled in an iron vessel; after settling, the clear part is thrown off and used when needed. Care must be taken, for if it will destroy weeds, it will just as certainly destroy elgums and border flowers if sprinkled on them. Weeds thus treated are said to disappear. —[Have any of our correspondents tried this?]

Pansies.—We have sent you a few Pansies, both fancy and show kinds, for your opinion.—J. COCKER & SONS, Aberdeen. [Among the show kinds, the best were Black Diamond, a deep velvety-maroon self, with a yellow eye; William Wallace, a dark violet-purple self, with an orange eye; and W. F. Gunn, yellow, blotched with maroon, all three fine kinds, though somewhat out of condition. The fancy varieties, one and all, are well varied as to colour, and will make effective border flowers.]

Silver-leaved Edging Plant.—As regards the inquiry of "R. J. K.," in last week's GARDEN (see p. 279), I would suggest that Veronica candida would suit his purpose perfectly. It is quite hardy, very beautiful, and easily propagated; it would make a good match, as to size, for Golden Feverfew, but not as regards colour; for white and yellow never look well together. This Veronica is also a useful plant for bedding or clumping; its short deep purple spikes of flower, resting on a cushion of silver, have a beautiful effect. There are two plants in cultivation under the names of candida and canescens, but whether they are distinct or not I am unable to say.—THOS. WILLIAMS.

Dwarf Plants for Rhododendron Beds.—Will you kindly oblige me by giving a list of dwarf plants suitable for planting in good peaty soil, beneath and among choice Rhododendrons and other American plants?—J. Q. R. [Numbers of beautiful dwarf plants may be grown with advantage in peat beds, as, for example, the Starflower (Tritialis), the white wood Lily (Trillium grandiflorum), variegated Partridge berry (Mitchella repens), the Blood root (Sanguinaria canadensis), the Podophyllis, the wood and the common Forget-me-nots, Rhexia virginica, Spigelia marylandica, Cypripedium spectabile and pubescens, Gaultheria procumbens, Linnaea borealis, Epigaea repens, and Epimedium in variety, Asarum microphylla, Asperula odorata, Campanula heterocera, Cornus canadensis, Dryas octopetala, Erpeton reniforme, Hepatica angulosa and the varieties of the common species, Ionopsisidium acule, various Mimulus, Nertera depressa, Nierembergia rivularis, Phlox reptans, Selaginella denticulata and helvetica, Smilacina biifolia, different kinds of Violas, and double Primroses in variety. For growing near the centres of large beds of Rhododendrons, &c., such plants as the Lilies, Gladioli, and Sparaxis pulcherrima are admirably suited.]

THE GARDEN IN THE HOUSE.

DINNER-TABLE DECORATION.

Baskets of Flowers.

SMALL baskets of flowers, if neatly arranged, form attractive ornaments on either the drawing-room or dining-room tables. Such baskets may consist of glass, china, or wicker-work, according to the taste of the purchaser. If of wicker-work, zinc pans should be made to fit into them, in order to hold damp sand or Moss in which the stems of flowers are to be placed. Clear glass, however, in my opinion, shows up the colours of flowers and the variously tinted foliage of the plants better than any other material; next to glass, I like plain white wicker baskets of graceful shape. In glass baskets the flowers should nestle among fresh green coloured Moss, instead of sand, which, when seen through glass, has a bad effect. In the case of wicker baskets, however, either material may be employed. The selections in reference to colours and flowers must be, of course, according to taste; some prefer Roses all of one colour, such as crimson; others like white and pink, and some mixed colours. *Maréchal Niel* may be used in such baskets with good effect, both in the form of half-opened buds set off with its own foliage, and the young brown leaves of other Roses. Round the handle of Rose baskets of this kind, may be twisted a spray of *Lygodium scandens*, but a piece of variegated Ivy, Japan Honeysuckle, or anything of that kind would look quite as effectively. Some mix different Ferns with Roses in preference to using their own foliage; but I like their own leaves best when the arrangement consists wholly of Roses; if for mixed flowers, then light fronds of Fern may be used with advantage. Nothing is more effective mixed through all kinds of arrangements in which yellow Roses are employed, be they blooms of *Maréchal Niel* or of *Gloire de Dijon*, than the young flower shoots of the common climbing Rose, so much employed for covering fences, &c.; the deep brown of the foliage making the yellow Roses look even more lovely, when in close contact with it, than they otherwise would be. I have arranged a small glass basket with pink Moss Rose buds and trusses of *Stephanotis*, the whole being toned down with light fronds of Maiden-hair Fern; no other Fern did I use, even round the edge and across the handle, and I felt much pleased with the result. The fronds which I employed for twisting round the handle being many shades lighter in colour than those used in other parts of the basket, diminished what sameness it might otherwise have had. In a small wicker basket, one single Water Lily, with a few sprays of blue *Forget-me-nots*, wild Grasses, and a few fronds of such British Ferns as *Asplenium*, *Adiantum-nigrum*, *A. Trichomanes*, *A. marinum*, and *Blechnum spicant*, or even the tips of the fronds of the common Brake, have a fine appearance. In an arrangement of this kind a small spray of light-coloured variegated Ivy might be twisted round the handle with good effect; but the variegation should be silvery not golden, as the latter would not look well placed against the pure white of the Lily.

A Vase of Roses.

To arrange a vase of Roses effectively is no easy matter. At many horticultural exhibitions a class is devoted to vases and epergnes of Roses, in which no other flower is allowed to compete, but any foliage that the decorator may be pleased to select may be added. I have seen many such stands staged, and when I first began to exhibit, I took a prize for one at the Crystal Palace in this class myself; but I can look back now, even to my own, and come to the conclusion that none of the exhibitions were so good as they ought to have been. All had the same heavy packed look, as if each exhibitor's great object had been to see how many dozen Roses could be packed into each tazza. After many trials in different ways, I find that no vase of Roses can be made to look well, unless each bloom and leaf have been previously wired. This may at first glance appear to be a heavy undertaking, and so it is, but the result will never be happy unless each leaf can be bent into any required curve, just as an artificial one is managed. Down the stem of the Rose should also be bound a stub wire, for the same purpose. The advantages of mounting Roses on wires is as follows: they can be bent out into any shape required;

they stand up more firmly than they otherwise would do; and last fresh just double the length of time they would if not so treated. Having before explained how a Rose should be wired, I need not again go over that ground. In arranging a March stand of Roses, each tier well shaded off, has a pretty appearance. Lay in the bottom dish deep pink and yellow kinds; in the upper, lighter shades; and the trumpet should be filled with buds of a still lighter tint; crimsons should be arranged in the same way. No flower looks handsomer, or is more useful for decorative purposes, than the Rose, but to make it so, it must be treated as I have above described, when the trouble will be well repaid by the effect produced.

A. HASSARD.

PRESERVING CUT FLOWERS.

It is not everyone who has the opportunity of cutting choice flowers from the plants just at the moment when they are required for use, and under such circumstances their preservation for a few hours, or even days, becomes a matter of importance. Even professional bouquet-makers, who receive supplies of fresh flowers every morning, find it necessary to adopt preservative measures; and I have often thought that if amateurs, more especially ladies, understood more thoroughly what precautions were necessary they would not be so often disappointed in their attempts to keep cut blossoms and foliage fresh. What, let us inquire, causes flowers to droop prematurely after being removed from the plant? Flowers, like leaves, absorb juices which reach them through the stem, and, while uncut, the supply is continuous, but the case is wholly different when they are cut; the supply of fluid then ceases while evaporation goes on, often more rapidly than before, especially if they are carried in the hand or placed in a dry atmosphere. To imitate, to some extent, the supply of moisture from below we place the stalks in water, in order to enable them to absorb moisture, to counteract the evaporation which is continually taking place, and, in many cases, such as those of Water Lilies, Iris, Narcissus, and similar flowers, which have thick succulent flower-stems, this is sufficient, as well as in those of hardy herbaceous and border plants, such as Wallflowers, Stocks, Violets, Mignonette, and scarlet Lobelias, all of which will continue to open fresh flower-buds for at least a week or ten days after being cut, especially if they have been removed with a sharp knife—for scissors crush the tubes of the stems, and so prevent their power of absorption. If the flowers are not immediately required they may be preserved fresh for several days by placing them in flat zinc or earthenware pans of water and living Sphagnum Moss; each flower should be placed separately, inserting its freshly cut stem through the Moss into the thin stratum of water below. The edges of the pan should be deep enough to over-top the flowers and foliage, and as each pan is filled, dip a cloth or napkin in cold spring water, and, after wringing it out, spread it evenly over the surface of the pan; if the latter is over a foot in diameter, some support must be placed in the centre, so as to keep the cloth off the flowers. Another excellent plan, where flowers have only to be kept fresh for a few hours, is to spread a wet cloth on a flat board, and to gently lay the flowers on it, covering the whole afterwards with a large glass shade or bell-glass, or if this is not at hand, an earthenware bowl, or even a wooden box may be inverted over them, and will answer nearly as well. This plan may also be modified in the case of bouquets not immediately required. In Covent Garden and elsewhere, the florists keep their choicest cut flowers in close fitting drawers or boxes lined with zinc, a layer of moist Sphagnum or Hypnum Moss, being laid on the bottom to keep the atmosphere cool and moist. Sometimes they are laid on wet Moss in a tray and placed on a cool moist cellar floor, where they will keep fresh for a considerable time. Any of these plans, the main object of which is to check evaporation, may be adopted in cases in which it is requisite to keep flowers for a short time after they are cut, and before they are required for use. Clear water is as good as anything for vases in which flowers are arranged, and if they are of transparent material nothing else can be used, but, if opaque, wet sand has the advantage of retaining the flowers more firmly in their places, while wet Moss continually throws off moisture

in the form of vapour, and thus assists in checking evaporation. Some recommend placing powdered charcoal and camphor in the water, and assert that flowers last longer when these are used than when in pure water only, but I consider that to be a mistake. Powdered charcoal will certainly do much towards keeping the water pure and free from bad smells for a considerable time, but, after many experiments, I have failed to discover any other advantages belonging to it; my flowers always keep best in clear water, changed every other morning, when the bases of the flower-stems are cut with a sharp knife, so as to afford every facility for active absorption of moisture. A weak solution of sal-ammoniac has been recommended for keeping flowers fresh, but, the advantages of using this, like those of other nostrums, are more apparent than real.

All fronds of Ferns and other foliage should be immersed in water as soon as cut, and they may afterwards be laid on a tray of Moss, as recommended for flowers. The latter may be temporarily revived by re-cutting the stalks and plunging them into water, as hot as the hand will bear it, for a few minutes; and, if covered with a bell-glass or inverted shade, they will revive sooner than without such covering. Another point connected with the duration of flowers in a cut state deserves more attention than it has hitherto received, and that is prevention of the flowers from becoming fertilised, as they seldom last long—even when left on the plants—after that takes place; besides, the pollen of some flowers, more especially that of Lilies, has a bad odour, and soils the purity of the petals when shed on them. Cultivators are aware of this fact, and either remove the anthers or stigma with a sharp pointed pair of scissors, or give them a dexterous touch with a gum brush, so as to prevent the escape of the pollen. Flowers so treated last much longer than those allowed to take their chance in the usual way, for it is a fact that many flowers droop directly the pollen is shed or the stigma fertilised. This is the case with Phalenopsis and other Orchids which, under ordinary circumstances, last fresh for fully a month or six weeks; but, directly a flower is fertilised—either intentionally, by insect agency, or by accident—the petals wither and collapse, and the flower quickly fades. Gumming is also resorted to by bouquet-makers in the case of Azaleas, zonal and fancy Pelargoniums, Rhododendrons, and other flowers of a fragile character. The process is extremely simple—a drop of gum or prepared mucilage is allowed to fall down into the centre of each flower; and after several are thus operated on they are placed in rows to dry. The gum sets in a mass at the base of the petals, and firmly unites them to the base of the stigma, so that the flowers last much longer than they otherwise would do, and the danger of the petals falling at an unlucky moment and leaving an ugly hole in the bouquet, wreath, vase, or other arrangement is, to a great extent, obviated. The natural power of endurance, after being cut, is very variable in flowers. Orchids, Heaths, Narcissus, Forget-me-nots, and Wallflowers, last from one to three or even four weeks, under good management, after being cut from the plants. Three or four days is a fair average duration for ordinary flowers; and, in making up arrangements, the individual capability of the different flowers employed to resist decay should be carefully studied. Camellias last well if skilfully handled, but no flower, if we except Gloxinias, is liable to suffer so soon from slight bruises or even gentle contact with other flowers as the Camellia. *Eucharis amazonica*, Gardenias, *Rondeletia*, *Euphorbia jacquiniæflora* and *E. splendens*, *Bouvardias*, *Lily of the Valley*, and *Christmas Roses*, all last well; as do also *Stephanotis*, *Heliotrope*, *Spiræa*, *Dielytra*, and most bulbous flowers, such as *Hyacinths*, *Amaryllis*, *Crinum*, and *Pancreatium fragrans*. F. W. B.

Leaf and Flower Impressions.—Oil a piece of white paper on one side; hold the side that is oiled over a lamp or pipe, not smoke till quite black; place the leaf on the black surface, as the veins and fibres of the leaf show plainer on the under part; now press it on all parts of the leaf with the fingers; then take up the leaf and put the black oiled sides on the page of a book (made for leaf impressions) with an extra piece of paper on the top to prevent smutting the opposite page; press it a few moments; then remove the green leaf, and the impression will be left on the page as beautiful as an engraving. Flowers of single corolla can be pressed in like manner. Many of the Geranium leaves make beautiful impressions. The impression book may be made still more interesting by giving botanical classifications of each leaf and flower.

THE KITCHEN GARDEN.

CAULIFLOWER-GROWING IN MARKET GARDENS.

This is, perhaps, the most important of market garden crops, and one to which many hundred acres of land are devoted in the vicinity of London. Cauliflowers were at one time all cut and sent into market; but now, Messrs. Crosse & Blackwell purchase the entire produce of extensive fields for pickling purposes. For ordinary market use, earliness is the great end to be attained, for not only is the price for early produce better than that for late, but there is an advantage in having the ground soon cleared, and ready for another crop. Market gardeners seldom make many sowings of Cauliflowers; one or two in autumn, and one or two in spring, being the usual number. The first autumn-sowing is made out of doors, sometime between the last week in August and the third week in September; and the second one, in frames, in the last week of September or first week in October. From these two sowings, Cauliflowers are obtained from the last week in April to the end of June. The first spring-sowing, if the autumn one is a failure, is made in a frame in the last week of February or first week of March, or it may be made in the open border, any time during the first fortnight of March; from this sowing, a crop is obtained, from the middle of June till August or September. The third sowing is commonly made in beds, in some open quarter, between the middle of April and the first week in May, in order to furnish an autumn crop.

Sowing and Winter Protection.

Different market gardeners have different times for sowing Cauliflowers, but it is universally understood that strong grossly grown plants do not stand the winter so well as medium-sized ones, and they are also more liable to "button." Moderate-sized plants are decidedly the best for mild winters, but in the event of very severe winters occurring, strong plants are the best. The first autumn sowing is made on a well sheltered piece of ground or a warm open quarter, in beds from 4 to 6 feet wide, and the majority of growers make this sowing in the second or third weeks of September. The young plants are allowed to remain in the seed bed until the end of October, or even the middle of November, according to the state of the weather; the milder it is the longer the plants are left in the seed-beds, in which they are kept rigidly clean, and the soil kept loose amongst them by means of the hoe. In the event of frosty weather setting in whilst the plants are in the seed-beds they are protected by means of mats supported on short stakes 18 inches above the ground. Of these stakes, five rows are inserted in the beds, viz., a row on either side, another in the middle, and other two, one being on either side of the middle row. Sometimes, a wooden board about 10 inches or a foot wide, is set on edge along the centres of the beds and two rows of short stakes are put in on either side to support it. This is practised in Mr. Broadbent's grounds in the Fulham Fields, and he considers it an efficient protection from frosty winds. Hoops and mats are also employed for a similar purpose. Where room is limited, and the weather appears mild, young Cauliflowers are often wintered in the beds where they were sown, or they are pricked off into raised beds of light soil not likely to be soaked with wet in winter. Here they are sometimes left unprotected, and at other times they are covered with hoops and mats. Continued dampness of soil and atmosphere is their worst enemy, as it induces growth so soft that it cannot withstand frost so well as that produced on high and dry ground. The frames in which Cauliflowers are wintered are put up in the middle of October in a sheltered spot sloping to the south. They are generally those in which Cucumbers have been grown during summer, and after they have been fixed in the positions they are to occupy, they are filled to within 8 inches of the top with ordinary soil firmly trampled down with the feet; over this hard bottoming 3 or 4 inches deep of a better kind of soil is sifted, and in this the Cauliflowers are planted 3 inches or so apart. Thus circumstanced, they are allowed to remain until the February following and early part of March without any further care beyond that of keeping the sashes shut in the event of sharp frosts, cold winds, hail, or rain, and tilting them up at front and back during favourable weather, and on very fine days drawing them

laid up when the ground was trenched, and where for a time they got good shelter, the ridges being eventually levelled by hoeing.

Successional Crops of Cauliflowers.

A third crop comes in three weeks after the second, and is either made from the late autumn sowing, or by means of plants wintered under hoops and mats in the open ground. A fourth plantation, which soon follows, is made from whatever plants are still left in the frames or outdoor beds. Cauliflowers are often planted on ground cropped with Radishes before the latter crop is marketable, and by the time it is so, and cleared off, the Cauliflowers will have gained good strength, when the ground will be intercropped with Lettuces. In other instances, fields are marked off into 5 feet wide beds, with 1 foot alleys between them, and these beds are sown with round-leaved Spinach. As soon as this is done, three rows of Cauliflowers are planted along the beds. The latter outgrow the former, which, by continual picking for market, is kept in check until it is eventually exhausted, leaving the Cauliflowers masters of the field. Autumn crops are obtained from spring sowings, which are thinned out a little in the seed-beds, and, when large enough for handling, are planted where they are to remain permanently. Should the weather be dry at planting time, about half-a-pint of water, or a little more, is given to each plant, and the sodden soil is soon afterwards freshened up by the hoe, thus, in some measure, preventing evaporation. Late Cauliflowers are nearly always intercropped with some other vegetable, such as Lettuces, French Beans, Celery, Seakale, &c. Mr. Myatt, of Deptford, however, departs from this rule, and thus saves much labour; for if he intercropped he would have to employ people to keep down weeds by means of the hoe; but when Cauliflowers alone occupy the ground, horse-hoes can be freely worked among the rows.

Varieties.

The Early Erfurt or Early London White is the variety used for the first crop by most market gardeners, but many others use the Walcheren for that purpose. Numbers, too, grow a quantity of both sorts for spring and early summer crops. The Walcheren, however, is the kind almost entirely grown for use after June, because it suffers less from drought than any other sort, and is not liable to "button." Snow's Winter White, an excellent sort, is, as a rule, regarded as a Broccoli; nevertheless, it has fine white solid heads, and is largely grown to succeed the Walcheren, being harder than that sort. Snow's White, if sown together with the Walcheren in April or May, makes a fine succession to it, and comes in usefully till January.

F.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Camomile Cultivation.—We have 2 acres of good gravelly soil, and have been advised to grow Camomile thereon for the London market. Would the cultivation of this plant be remunerative? Is there much trouble attached to it? and where could I get the fullest information as to cultivation and harvesting? Perhaps some of your correspondents will oblige me with answers to these questions.—B. R.

Veitch's Autumn Cauliflower.—My experience this season with this excellent variety of Cauliflower is the same as that of Mr. Gilbert (p. 276), namely, that it has stood the dry summer better than the Walcheren or any other sort. Having the advantage lately of irrigating the kitchen garden here, Veitch's has come in for a good soaking at times, and is now furnishing nice close heads, as white as snow, and of excellent flavour. The spring-planted Walcheren, and other varieties of Cauliflowers, showed miserable, tough, burnt-up heads all through the season, and, even now, the latest planted are not to be compared with Veitch's.—Wm. TILLERY, *Witchbeck*.

Late Peas.—The late sown Peas have with us been a sad failure, for, although well watered in July and August, the old favourites such as Ne Plus Ultra, Veitch's Perfection, and Omega, have only furnished very scanty dishes. In the middle of July, I sowed a good breadth of early dwarf Peas, such as Alpha, Miltum in Parvo, and Little Gem, and, being well-irrigated, they are now showing plenty of nice pods ready for gathering. Although these early dwarf Peas are not so prolific as the taller-growing sorts, they can be sown in rows much closer together, which makes up for the deficiency.—Wm. TILLERY, *Witchbeck*.

Ne Plus Ultra Pea.—As a late summer Pea, Mr. Saul, of Stourton, writes to the *Florist*, that he has not as yet found any other kind to excel this. I have it now (Aug. 15), and have had it for some weeks in very fine condition, notwithstanding the long-continued dry weather. It is a most abundant bearer, of superior flavour, and remains a long time fit for use—all great recommendations in its favour. Those who wish to have it fine I would advise to save their own seed, and, in doing so, to pay attention to the matter by selecting only the finest pods. By this means they will secure good, genuine seed, and by sowing thinly in rows about 6 feet apart on deeply-dug ground, they will get good crops of Peas of the finest quality, well repaying any little pains or labour bestowed on them.

A POPULAR THEORY EXPLODED.

THE *Revue Scientifique* gives a long and interesting account of the researches into the respiration of plants, which M. Corenwinder has communicated to the Société des Sciences of Lille. For many years the functions of the vegetable kingdom were represented as being of an opposite kind to those of animals. Plants grew to furnish food for animals, and to render animal life possible; they formed intermediate principles which animal life destroyed; animal excretions were the natural nutriment required for vegetable life, and plants purified the air which animals deteriorated; and finally, respiration, the most continuous function of our organism, was in animals a process of absorbing oxygen and evolving carbonic acid, and in plants an absorption of carbonic acid and an evolution of oxygen. The idea arising from these views was that of harmonious opposition. Claude Bernard's experiments showing the formation of one of the most important of the intermediate principles, sugar, in the liver of animals, overthrew this theory, and suggested new views in harmony with the general tendencies of science, and led to comparisons of plants and animals, founded upon their resemblances rather than upon their differences. In tracing these resemblances, considerable difficulties were experienced in relation to the function of respiration, and it is these which M. Corenwinder claims to have removed. The reviewer remarks that since the respiration of plants was first regarded as an exhalation of oxygen derived from the carbonic acid of the air, experiments, which are now old, materially limited the force of this explanation. It has been long known that this mode of respiration depends on the action of solar rays, and is confined to portions of plants containing the green matter chlorophyl. It was then discovered that flowers not coloured green, and even green parts in the dark, did not limit their action to absorbing carbonic acid and setting free its oxygen; on the contrary, they absorbed oxygen and exhaled carbonic acid as animals do. Hence arose the ascription to plants of two modes of respiration, one nocturnal, and the other diurnal, the latter being regarded as the chief or true respiratory process. M. Corenwinder's investigations show that what has been considered diurnal respiration—viz., absorption of carbonic acid by the chlorophyl—is a digestive act, as Claude Bernard supposed, and that the real respiration of plants resembles that of animals. Buds, young shoots, and growing leaves for a certain time absorb oxygen and exhale carbonic acid in an ostensible way, and without interruption by day or night, except in the spring, when the nocturnal temperature is low, and the process is scarcely apparent. Light and heat accelerate it. As the buds or leaves grow beyond a certain point of development, this absorption of oxygen and exhalation of carbonic acid diminishes sensibly, and ceases to be apparent when they are fully grown. The amount of this action observable in any plant is proportioned to the quantity of leaf, &c., in active growth. The limit beyond which plants cease to exhale carbonic acid in an ostensible way during the day, varies much according to the species, some manifesting it a long while, others losing the faculty quickly. In the first category M. Corenwinder places *Dielytra spectabilis*, and in the latter Beetroot leaves.

To ascertain why the exhalation of carbonic acid apparently ceased in adult leaves, when it ought, by analogy with animals, to be in most vigour, M. Corenwinder proceeded to analyse the leaf contents in different periods of growth. Lilac and Maple leaves were used in two sets of observations extending from April 15 to October 31. The proportion of water in leaves diminishes as the season advances, but the decrease is not regular, considerable rains occasionally throwing it back. Operating upon dried leaves, M. Corenwinder found that the proportions of nitrogenous and carbonaceous matters varied according to the stage of growth, and also according to the nature of the plants; Maple, for example, containing more nitrogenous matter than Lilac, and country trees more than town ones. Omitting the tabular statements of analyses, the general result was that during the growth of leaves, their proportion of nitrogenous to other matters diminishes rapidly. It is at a maximum when they first emerge from the bud, it lessens quickly about the beginning of July, when the fruit of the Lilac is formed. After this it is slightly variable, but seems to experience a small increase as the leaves approach maturity, and is at a minimum when that period is reached. At the time of the Lilac leaves falling, their nitrogenous matter amounts to about one-third of the proportion they had in the beginning; in Maple it is a trifle more. The carbonaceous matter augments rapidly from the moment the leaves emerge from the buds till the completion of their growth, which, in the Lilac, is when the flowers are nearly open. There is a slight increase beyond this up to September, and then, in Maple, a sensible depression, and the maximum proportion is at the time of the fall when they have lost a good deal of their nitrogenous matter. The quantity of Ash increases rapidly up to June, after which it is less pronounced. Withered leaves of Maple contain less mineral matter than those of Lilac, which lose a slight proportion in

the course of their existence—probably through rains carrying off some of their soluble salts.

It now remains to connect these facts of analysis with the life history of the plants. During the entire growth period the nitrogenous matters are very abundant, probably organised, and endowed with an existence independent of the vegetable cells. They exercise the animal function of respiration, which then is the predominant operation. At first, the carbonic acid resulting from this process is only partly retained by the reducing action of the chlorophyl. Thus the young plant exposed to light and air exhales an excess of carbonic acid. In the second period the relative proportion of nitrogenous matters diminishes and the carbonaceous matters increase. The plant then only exhales a small quantity of carbonic acid, the bulk of it being retained by the chlorophyl, which decomposes it and fixes the carbon. At a later date the carbonic acid ceases to appear, the gas being absorbed by the chlorophyl as quickly as it is evolved by respiration. The respiratory phenomena are then masked, and can only be revealed by indirect processes. In an experiment of Bous-singault it was found that leaves placed in a bell-glass containing pure hydrogen mixed with a little carbonic acid, in a room feebly illuminated, gave out a little oxygen, showing that the assimilation of carbon had not ceased, which it only does in total darkness. It is also known that in a similar amount of light leaves in a glass full of air give out carbonic acid in inspiring oxygen; and, putting the two facts together, it appears that the two functions of the plant—respiration and assimilation of carbon—are simultaneous, but that the last becomes so attenuated that it cannot completely mask the effects of the former. M. Corenwinder finds support for his theory in the fact that the white-tufted leaves found in a variety of Maize, which contain no chlorophyl, have not the faculty of sensibly absorbing carbonic acid and exhaling oxygen as the green and purple Maize leaves have in sunlight; but they do exhale sensible quantities of carbonic acid in daylight. Senebier had noticed that the red and yellow tufts of the tricoloured Amaranth did not give off oxygen when exposed to the sun, but that the leaves of the red Amaranth had this property. So leaves naturally green, but changing to red at the end of their lives, such as those of the Virginian Creeper, completely cease to absorb carbonic acid and exhale oxygen. Faded-leaves, as M. Corenwinder found, emit carbonic acid, though not as an act of vitality, but of decay. Analysing some white leaves gathered from a Maple, and also some green ones from the same tree, the former were found to contain in 100 parts (dried) 17.06 of nitrogenous matter, and the latter only 13.75. Thus white leaves are proportionately richer in nitrogenous matter than green ones, the latter being the richer in carbonaceous matter. Respiration he considers the function of the organised nitrogenous matter; assimilation of carbon that of organised matter chiefly, if not solely, formed of ternary compounds. For a more detailed exposition of his processes and results the original papers may be consulted. If his opinions should be confirmed, we shall have the curious fact of organisms digesting and assimilating as food that which is an excretion of their own respiratory system.—*Academy*.

The Sleep of Plants.—With a great number of plants, both leaves and flowers assume during the night a very different position from that which they affect during the day. To this curious phenomenon Linnaeus applies the name of vegetable sleep. Thus, in the case of the False Acacia, the leaves of which hang towards the ground during the night, the fifteen or twenty-one leaflets which compose them spread themselves out horizontally at the rising of the sun, and eventually raise themselves up in such a manner as to touch each other by their superior surfaces. The contrary takes place with the Colutea, so common in copses; being spread out horizontally during the day, in the night the leaflets raise themselves perpendicularly upon the petiole, and stand opposite each other by their upper surfaces. With the Cassia marylandica the situation of the leaflets is exactly contrary to that occupied by the leaflets of the Colutea; these, being also horizontal during the daytime, turn themselves down backwards in the night until they touch each other by their lower surfaces. With the sensitive plant *Mimosa pudica*, and its congeners, the leaflets of the four feathery composing its leaves being spread out during the day, bend themselves during the night along the petioles, covering each other, the lower face being above. In the case of the *Tephrosia caribæa*, the movement is quite opposite, the leaflets bending themselves from the summit of the leaf towards the base. This curious faculty, indeed, shows itself generally, and in the highest degree, among the leguminous plants. It is but rarely found in other families, and even then is usually isolated in some genera, such as the *Oxalis*, for example. Philosophers have hitherto been unable to explain, satisfactorily, the sleep of leaves and flowers, spontaneous and excited movements, &c. A crowd of hypotheses,

many of them very ingenious, have appeared from time to time, but they destroy each other and disappear before serious examination. The author who has most successfully applied himself to these studies, Mons. Dutrochet, affirms, in order to explain the phenomena, that plants are furnished, the same as animals, with nervous systems, and in truth, the explanation which he gives, following a vast number of experiences and delicate anatomical dissections, appear to favour that conjecture.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

Hardy Flowers, Alpine Plants, and the Wild Garden.

THE fine old *Stenactis speciosus* is now gay with its second crop of bloom, which would have been all the stronger if the stems had been removed from the plants as soon as the earlier blossoms were over. *Rudbeckia fulgida* and *Newmanni* (not *hirta*—it is only a biennial) are still wonderfully bright, and, what is more, their lustre is undiminished, even by a drenching rain; the deep golden florets of the ray contrast beautifully with the dark chocolate coloured disk; dwarf in habit, so rigid in growth as to require no staking, they have, however, one fault, that, being surface rooters, they are liable to suffer, and have, indeed, suffered much this season, from drought. So closely related to these, as at one time to have been included in the genus, are the lovely *Echinaceas*; the freest grower and the one most generally met with is *E. intermedia*; with us it attains a height of 3 feet or more, and when each stem is terminated with a crimson-rayed flower, fully 5 inches in diameter, it is certainly one of the most effective and beautiful hardy plants to be seen in bloom at this season; the other two species, viz., *E. purpurea* and *E. serotina*, are dwarfer, and much more rarely seen, as is also the *E. angustifolia*, the true form of which is still only to be found, we believe, in cultivation with our old friend, Mr. Leeds, of Manchester. The *Heleniums* are all pretty, most abundant bloomers, and well adapted for the back row of the herbaceous border, or for enlivening the shrubbery with their masses of golden bloom; amongst tall ones, autumnale and commutatum are the best, and among the dwarf, *Bolanderi* and the true *atropurpureum* are equally desirable. Nor must we omit the double perennial Sunflower (*Helianthus multiflorus plenus*). Though some of the early blooming *Eryngiums* have disappeared, we have yet *E. amethystinum*, glowing with its blue metallic lustre, which renders its name so appropriate; *E. glomeratum* and *creticum* are still enjoying a fair share of beauty; and *E. maritimum*, our own "Sea Holly," is yet attractive, owing to its white peculiarly-contorted foliage; it is, however, a dwarf when compared with the foregoing species. *Campanulas* have nearly passed, but the noble old *pyramidalis*, which, under favourable culture, sends up its towering spikes to a height of 6 feet, is still an object of beauty; as is also the dwarf *C. isophylla*, at one time known by the very appropriate name of *floribunda*. It is a neat clustered plant for a rockery, with much larger flowers than old *garganica* or *Cymbalaria*; it does not ripen seeds—at least has not done so with me—but strikes freely in spring, with the aid of a gentle bottom-heat. *Phloxes*, whose names and varieties are legion, are also beautiful, but these, as well as the many showy hybrid *Pentstemons*, have long since been relegated to the florists' department, so I shall not deal with them. *Scabiosa caucasica*, with its large, flat, expanded capitula of lavender blossoms, is a plant well worth cultivation, as is also *S. Gram-muntia*, whose finely cut foliage is effective and pretty, independent of its blue flowers. Both these may be freely produced from seed; but beware of hybridisation in the latter—the former always comes true. *Lobelias*, such as *ignea* (with its dark foliage) and old *cardinalis*, both of which have intensely brilliant scarlet flowers, as well as the numberless fine hybrids (in all shades of puce, purple, and blue) are, where they thrive well, the gayest of the gay. They, however, have their likes and dislikes, and with us, will neither flourish in summer, nor stand through even the mildest of winters. The *Statice*s, or Sea Lavenders, are all fine autumn plants, adapted equally well for the border and the bouquet; nay, more, not unfrequently, in a dried state, constituting a very elegant feature in the floral decoration of ladies' bonnets. *S. Tormentilla*, *scoparia*, and *Besseriana*, are tall growers, as compared with *S. latifolia*, *elata*, *Smithi*, and *Willdenowii*. Besides these, we have many dwarf species, some not exceeding 3 inches in height, and all are beautiful. The large ones are most impatient of removal, and require two or three years to attain their full development, after such an ordeal. As I now write, one of our finest and most effective plants, in respect of habit, as well as bloom, is the Japanese *Polygonum Sieboldi*, sometimes called also *cuspidatum*; it has this season attained a height of 9 or 10 feet, carrying its foliage from the very base, in fully developed perfection, and now

its beautiful branches are pendent in graceful curves, with the weight of the feathery flowers, individually small, and inconspicuous, but in mass and arrangement, the very perfection of beauty. One fault it has is, that it is a sad Rambler, so much so, that in a very few years, a single plant would cover half an acre of ground, and it will hold its own with a vigour and persistency that annihilates all competitors. A closely-allied species, though quite dwarf in habit, is *Polygonum japonicum*, whose broadly heart-shaped leaves are beautifully crimped at the margins. Nor must we omit the lovely pink-flowered *P. vacillifolium*, whose dwarf creeping habit, and trailing stems, covered with small light green leaves, decked all over with charming spikes, is a picture of beauty. Some may have tried its culture unsuccessfully; to such, we would say, that it will be found perfectly at home in a bed composed of half peat, and half leaf soil, with a nice sprinkling of sharp sand in it. Amongst *Cyclamens*, *europæum*, in its pink and white forms, appears (like the *Colchicums*), as it were, to form a connecting link between the autumn and the spring. Old established plants, and those I now have in my eye, have grown in the same place for twenty years to my knowledge, and, possibly, their age may be nearer forty than twenty, are now a mass of bloom; and, in early spring, they will be covered with quantities of their lovely painted leaves, for which alone, independent of the flowers, their culture is desirable. The *Tritoma Uvaria*, and other varieties, are now in full blossom; and well do they merit the important position they have attained, being, without exception, the grandest autumn decorative plant which we have. Wondrous, too, is the variety which the *Gladiolus* has assumed under the hands of the florists who have made its hybridisation a speciality. This dry season has, however, been anything but favourable to their vigorous growth, many of them having been attacked with red spider in the early stages of their development. *Tritonia aurea*, or *Crococsmia* as it is sometimes called, is a plant supposed by many to be tender; but it has withstood the severity of our winters for the past five years, and, thus grown, forms an equally valuable plant out of doors as it has hitherto done in the greenhouse for autumn decoration. The *Commelynas*—viz., *celestis*, *scapigera*, and *angustifolia*—when grown near the *Tritonia*, form a lovely contrast when the azure-blue flowers mix with the orange blossoms of the latter. They have fascicles of thick fleshy roots, and ought to be planted pretty deeply, else they are apt to suffer from the frost. The *Marvel of Peru* (*Mirabilis Jalapa*), though generally grown as an annual, is really a good perennial, which, under the protective influence of tolerably deep planting, will produce year after year an increasingly strong growth, accompanied by an early and long protracted bloom; the best plan is to lift the roots after the first year's growth, and store them away as we do Dahlias, replanting again in early spring, and allowing about 6 inches of soil above the crown. Though Dahlias, as generally recognised, are not within our province, yet there are some old species that are worth growing, and none more so than the dwarf lax-growing one known by the various names of *D. glabrata*, *repens*, and *scapigera*; it has a fascicled root, the same as its more familiar congeners, and is perfectly hardy if treated as the *Marvel of Peru*; its tiny flowers, no bigger than a penny-piece, vary in tint from a rosy-white to a deep lavender-purple; and are sufficiently neat to answer even for a button-hole bouquet; they are gracefully supported on long slender stalks, and continue to flower freely to the end of October. Of more lofty growth are *D. coccinea* and *Cervantesi*; of these the latter is the more desirable on account of its finer cut foliage and glaucous tint, which at once distinguishes it from the common forms; but, for grand foliage their giant relation, *D. imperialis*, bears the palm; unfortunately, its blossoms are so late that they are always "nipped" by the bud." *Lilium tigrinum splendens* is one of the finest of our autumn Lilies, we have it now full 5 feet high, with some twenty or more flowers in a panicle, still expanding into rare beauty, reminding me of a large group I saw about this time last year in Mr. Ware's nursery, that was a conspicuous object full half a mile off; possibly some of my readers may say this is a dull sort of calendar of operations. In my next article I may indulge in drier details, more in keeping with such a title, and give time for a change in the floral panorama, ere I analyse its individual parts again.—J. C. NIVEN, *Botanic Gardens, Hull*.

The Flower Garden and Pleasure Grounds.

With the exception of keeping everything connected with this department in the best possible order, little at present is required to be done. The flower beds are still in full floral beauty, even more so than is usually the case at the present advanced period of the year—a circumstance possibly owing to the protracted drought of the earlier part of the season having retarded for a very considerable time the development of the plants, the suppressed energies of which are now, as it were, set at liberty by the genial and somewhat copious rains, which we have recently experienced;

the consequence is, the floral display in flower gardens is more gorgeous and abundant than it has been at any other period during the present season; and, in order to maintain this desirable result, as long as possible, the greatest degree of neatness and order should pervade the entire department. In cases in which it may have been difficult, or even impossible, to obtain at an earlier period, a sufficiency of cuttings of any variety of bedding plants, this deficiency may now be made good, and the propagation of all such plants should be brought to a close as speedily as possible. Even bedding *Calceolarias*, which are always found to succeed best when the cuttings are inserted somewhat late, may soon, or even now, be commenced with. These plants are most successfully propagated in cold pits or frames, either in pots or otherwise. If pots are used, they may be some 8 inches in diameter, and should be well drained, and the soil may be composed of one-half leaf-mould finely sifted, while the other half may be sharp river or pit sand, which will answer the purpose quite as well as the best silver-sand. They may be wintered in the pits or frames in which they have been struck, and will of course require the protection of mats, &c., when the weather is severe. Treated thus, they will generally be found by the end of March to be in good order for transplanting into temporary pits or trenches, where they can have the necessary protection which they may require during very severe weather; and, from such quarters, they may be safely transferred to the flower-beds early in May. Wherever it is contemplated to transplant large evergreen shrubs or trees, the present is a suitable time for performing such operations, which may, nevertheless, be successfully performed at almost any season; indeed, various opinions exist as to the best time for transplanting large Hollies, and other evergreens; but, all things considered, the present time, or from this until the middle of November, is, doubtless, the most convenient, and probably the best time to perform such operations. Up to November the soil retains sufficient warmth to encourage the development of fresh roots, and to thus repair unavoidable injuries resulting from the operation of transplanting before very severe weather is likely to set in. It will still be necessary to keep lawns constantly mown and rolled, although mowing will be less frequently necessary than it has hitherto been. Leaves have this season commenced to fall sooner than is generally the case; gravel walks must, therefore, be frequently swept and afterwards well-rolled, in order to secure solidity and smoothness of surface.—P. GRIEVE, *Culford, Burg St. Edmunds*.

Indoor Fruit Department.

Vines in pots, which were thoroughly ripened a month ago, may now be placed in a gentle heat, i.e., if Grapes are wanted in March and April; select those showing plump prominent eyes and well ripened canes for the first batch, using Black Hamburgh in the dark section, and Royal Muscadine in the white division. Wash the canes with a hard brush, employing soft-soapy water, and clear the surface-soil away well down about the roots; then fill up to within an inch of the rim of the pot with a compost consisting of cow-mannure and horse droppings mixed with a little fresh loam. The roots run freely and feed greedily in a compost of this kind, and at every application of water much valuable matter is washed down to the lower roots. Early growth is much facilitated by the pots being plunged in some fermenting material in which a bottom-heat of 70° can be maintained—say, here and there in a Pine bed where there is room. Where such means are unavailable set the pots on the top of hot-water pipes. A temperature of 60° by day, and 50° at night, will be found to be sufficient for the first fortnight. Dew the canes overhead both morning and afternoon. The object and advantage of forcing pot Vines is to be able to cut new Grapes at Easter, or at any other special time, when only a few are required, and when a large Vinery-ful would be too many. Vine culture, in pots, also saves Vines permanently planted out, which often suffer much, if forced, very early. Permanent Vines, if started into growth for a succession of years, in October or November, soon succumb to such unnatural treatment. The roots on which so much depends, fail to act in company with the top, and failure is the inevitable result. Pot Vines may be conveniently accommodated in an odd corner of any stove, and when eight, ten, and twelve nice bunches can be obtained from them, the original cost and after attention are fully repaid. Keep all retarded Grapes free from decaying berries, and do not let any decayed leaves remain on the Vines, or lie about on the surface of the border, as these collect and harbour damp, and otherwise render the atmosphere unwholesome. Pine suckers may yet be taken off, potted, placed in some close, warm, moist corner, and be treated as former instalments. All canvas shadings may now be removed, and carefully stored in some dry place until needed another season. Wash off any paint mixture which may have been put on the glass, and, in future, admit full

light from every possible inlet. Vines, and other deciduous climbers, which have done good service throughout the past hot summer in the way of shading, will now be opportunely casting their foliage, and will, therefore, prove no obstruction to light. The rods of these should be wintered outside—i.e., if provision exists for doing so—for, when kept in a warm temperature, they are constantly in excitement, and the result, in every way, unsatisfactory. Mushroom-houses, in which newly-spawned beds are at work, should have the atmosphere well charged with moisture, by means of evaporating troughs, and the frequent damping of all available surfaces.—J. MITCH. *Clonsford.*

Peaches, Melons, and Strawberries.

In late Peach-houses, in which the fruit has all been gathered, a slight watering should be given to moisten the surface; if watering has been well followed up, soakings of water should be avoided at this season until the leaves have fallen and the wood is ripe. Late Admirable is nearly over; but Lady Palmerston is just being gathered from standard trees. The earliest house will now be fit to prune, clean, and train for starting to force in another month or so. A good soaking of water should also be given if it is known that there is good drainage in the border. Moisture is essential to prevent dropping of the buds, and to assist in their setting—in short, to maintain the vigour of the trees. One of the most useful and simple dressings which can be applied to the trees is quick-lime mixed with a little clay and water to the consistence of paint; lime itself would not harm the buds in the least, but clay subdues the colour; if this is applied year after year, it will keep the trees clean from most insects; oils and soaps are unsafe, unless used with caution. In late houses, bedding plants or *Fuchsias* may be wintered, without injury to the trees. Melons, in low pits, will soon be over, but in trellised houses, heated by fire-heat, there is yet at least a month during which fruit may swell and ripen; keep the foliage trim, and a steady heat at the root, so that cautious waterings may be given, to keep the foliage in good health, and to swell off remaining fruits. With the late moist weather, Strawberries have made rapid progress; every encouragement must, therefore, be given to late potted sorts, in order to induce them to fill their pots with roots; let them have room, and do not over water them, an important matter, as after the pots are well filled, the crowns swell and ripen; avoid stimulants at this period, these are unnecessary where good soil has been used. Cut off all runners and dress off with the finger and thumb all side growths, so that the single central crown may be strengthened. Marguerite is a useful early sort for forcing; with us it has a strong tendency to push up secondary crowns, which are delusive, inasmuch as they give the plant the appearance of luxuriance, and owing to the pot being well furnished with foliage, there is a fine prospect of fruitfulness; but one strong crown is worth half-a-dozen weak ones, even though the foliage is sparse. In the north, early potting of Strawberries is essential, and of decided benefit to the plants, inasmuch as the summers are cooler and more moist than in the south; but in the latter, later potting may be performed with perfect success, as, on the whole, the growth is made more rapidly as the days shorten and the atmosphere gets moist; the Strawberry delights in moisture, and plants potted in early summer have to withstand the dry summer heats.—W. D., *Canford.*

Harvesting Fruits.

The harvesting of fruits, though generally hurried through, should be gone about with care and leisure. It is imprudence approaching to recklessness to sacrifice the produce of a year's anxiety and toil in order to save a day or so in harvesting fruit safely. Yet this is what is constantly being done. Fruit cannot be got on too fast; while, on the contrary, it can hardly be gathered and harvested too slowly. Even the Peach season extends from September to November; the Apple, from July to November; and Pears, from June till the frosts of winter threaten them with destruction. It is general and all-at-once gatherings that are the ruin of fruits. Almost every fruit has its own special time when it may be best gathered. That set time can only be learned by experience; but the merest novice knows that there are wide differences between the seasons of maturity of the different varieties of our main crops of fruits, such as Apples, Pears, Plums. As generally harvested, not half enough allowance is made for these and other differences. A more general knowledge concerning the ripening of fruits would extend the harvesting season over many months instead of, as now, crowding the heaviest part of it into a week or so towards the end of September. Fruit should be softly and tenderly handled, and laid in single file in baskets or trays as gathered, and carried by hand to the fruit or store-room. It should likewise be sorted, as gathered, into sizes and qualities—keepers and not keepers especially being stored apart. All small, deformed fruit should have

a place to themselves—a shelf, or such like place, for the awkward squad. The other fruit would not only keep, but look so much better by being rid of the refuse; and a fruit-room should not only be clean, cool, dry, of even temperature, and frost-proof, but should also be ornamental. A good arrangement is a series of shelves, about a yard or 4 feet wide, around the sides, a broad table in the middle, and a good wide path all round. The fruit in season can then always be displayed on the centre table, and the whole place with all in it becomes a source of pleasure and honest horticultural pride to its possessor. There are few more interesting things in a well-furnished garden than a neatly arranged, orderly maintained, well-filled fruit-room, such as may be seen at Sandringham, and in other great gardens; for it is quite a mistake to suppose that a fruit-room must be large to be interesting, or well suited for the safe keeping, and orderly and safe storing of fruit. On the contrary, there is no good reason why each garden, large or small, should not have a suitable room to receive and store its produce.—D. T. FISH.

Indoor Bulbs.

It is high time a few Crocuses, Snowdrops, and Squills, were potted up for early blooming. By the use of some of the autumn-blooming species, Crocuses may be had in flower successively from September to April. The autumn-flowering kinds will flower quite as early in the open ground as in pots, but during autumn the weather is often so unfavourable as to soon destroy them in the open ground; whereas, if some be grown under glass, their beauty is considerably prolonged. Unfortunately, the autumn and winter-blooming Crocuses have been so much banished from our gardens, that it is only in certain places they can now be met with. The autumn blooming kinds are *C. autumnalis*, purplish-blue; *byzantium*, lilac, deepening to purple; *nudiflorus*, violet-purple; *sativus* (the Saffron Crocus), purple; *serotinus*, blue; and *speciosus*, blue, also very handsome. What may be termed a winter-blooming section, flowering later than the preceding, and forming a kind of intermediate floral group includes *Imperati*, violet, fawn, and white, very distinct and fine; *chrysanthus*, orange-yellow; and *nivalis*, white. The spring-flowering species, though very pretty, cannot compare with the fine garden varieties now so extensively grown, with the exception of *C. reticulatus* (Cloth of Gold) and *C. biflorus*, the Scotch Crocus, both of which are very early, and characterised by great freedom of bloom. Cloth of Gold is the only yellow variety suitable for growing in pots; the large yellow spring-flowering Crocus does not bloom so freely under glass as in the open ground. There are now many very fine varieties of Crocus verus, producing very large and showy flowers; and among these, as especially suitable for pot culture, may be selected the following:—*Albion*, white, very large; *David Rizzio*, deep purple; *La Majesteuse*, heavily striped with violet on a white ground; *Lamplighter*, bright purple; *Lilacinus superbus*, bright blue; *Mont Blanc*, pure white; *Ne Plus Ultra*, lilac-purple, edged with white; *Othello*, blue-purple; *Pride of Albion*, white, striped purple, very large and fine; *Sir J. Franklin*, large, dark purple; and *Sir Walter Scott*, very delicately pencilled with violet, one of the most beautiful varieties in cultivation. Six bulbs of any one variety, or even eight, should be placed in a 18-pot, using a good soil; and, with but little trouble, they can be had in full bloom in early spring. The Snowdrop should be grown in pots, a dozen bulbs being placed in the same sized pot as that recommended for the Crocus. The double variety produces the largest flowers, but some of both should be used. With the Snowdrop can be associated the charming spring Snowflake (*Leucojum vernum*) with its chaste Snowdrop-like blossoms, which can be got in bloom throughout March. Too much cannot be written in praise of the early-blooming Squills, especially *S. amena*, *S. bifolia* and its white variety, and *S. sibirica*. The last has been well designated "the brightest and most beautiful of our early spring flowers," and, like *Myosotis dissitiflora*, it affords a lovely hue of blue in the early spring. The earliest to flower is *S. bifolia*, smaller and much less intense in colour than *S. sibirica*, but most charming. *S. amena* is the latest of the three, but only just succeeding the others. Some of each of these should be potted up about six or eight bulbs in a pot, and, like the Snowdrop, they can be managed with but little difficulty. The fragrant Polyanthus *Narcissus* must not be excluded from our list. Two or three bulbs should be placed in a pot, the size of which should be regulated according to the dimensions of the bulbs; one bulb only in a pot is not sufficient to make an effective display. Perhaps of all spring-flowering bulbs grown in pots the Polyanthus *Narcissus* is the most easily managed; but the better the compost, the finer and more plentiful will be the fragrant flowers. There is so very much sameness of character among the varieties, that it is only necessary to indicate a few, and they should be *Bazelman Major*, *Gloriosa*, *Grand Primo*, and *Grand Soleil d'Or*. Others may be added, but the foregoing are fine and distinct. There are two forms of the

border Narcissus that are especially well adapted for cultivation in pots, though they lack the fragrance of the Polyanthus section. These are Ajax bicolor, or the Trompet Sulphur of the Dutch growers, the tube golden yellow, the petal pale sulphur, and Ajax maxims, the Trompet Major of the Dutch growers, deep golden yellow; flowers, very large. These are actually what are termed border varieties, but they come so fine in pots, and are of such a very showy character, that they deserve to be highly recommended for that purpose. If possible, imported roots of these should be obtained, as they are certain to flower, and are much more reliable in pots than when grown in this country. The pretty Narcissus Bulbocodium and the equally pretty N. minor should not be overlooked; nor should the richly fragrant Jonquil be excluded from our list, especially what is known as the Single Sweet-scented. If as soon as all these have done blooming they are carefully transplanted to the open border, they will establish themselves there, and gild the opening days of spring with their bright blossoms for many years to come.

The Kitchen Garden.

No cultivator who aims at producing first-class vegetables in all seasons, ought to be satisfied with less than from 2 to 3 feet in depth of good soil. It may not be possible to secure this in some gardens all at once, but if this object is kept steadily in view, and as far as possible acted upon, a steady and progressive improvement will certainly take place, which will soon show itself in the improvement of the crops. The two principal ways of increasing the depth of the soil available for the roots of plants are, firstly, deep trenching in autumn; and, to this end, every spare moment that can be abstracted from ordinary routine work should be occupied in turning up deeply every vacant piece of land, and throwing it up roughly, to expose as large a surface as possible to the action of the atmosphere. Where the sub-soil is decidedly bad, be content with bringing up only an inch or so to the surface, but stir the bottom up well with a strong steel fork; even this will let in the air and allow the water to percolate more freely through it than before, and will make it more suitable for bringing to the surface at the next trenching. In this way a vast improvement might be gradually made in many gardens, and I am confident that if the practice was generally carried out, the result in improved crops in all seasons would be patent to even a casual observer. "Where there's a will there's a way," and any cultivator once impressed with the necessity of deep culture, will find a way to accomplish his object—gradually and slowly it may probably be, but none the less surely on that account. The second mode of deepening and improving a poor soil is by adding to the surface everything that can be obtained that has any value either as a manurial or mechanical agent; and there are so many substances (often looked upon as valueless), about gardens, especially at this season, which, if properly utilised, would be of the greatest value in any persistent scheme of improvement. All refuse vegetable matter, whether living or dead, should be carefully treasured up, as it contains within itself the nucleus of future crops. There is such a number of substances usually called rubbish, such as the cleanings of ditches, trimmings of banks, roads, and hedges, all so easily obtained as to render the improvement of even a bad soil not so difficult a matter as at first sight it might appear. Amongst the most useful of mechanical agents for ameliorating a heavy soil may be mentioned all kinds of ashes and charred earth or clay, lime and mortar rubbish, and the *débris* from old buildings when taken down; whilst light sandy soil cannot have anything so beneficially applied to it for improving its staple as a good dressing of clay spread over the surface in autumn after trenching, and, after exposure to the action of the weather all winter, lightly forking it in in the spring before cropping. Where French Beans are in demand all the winter, two or three dozen pots may be planted to succeed those planted in frames; by making successional plantings every three weeks or so, the supply will be kept up. A position near the glass will be requisite, as also a moist atmosphere and a night temperature of not less than 60°. 21-sized pots are a handy size, they should be half filled with good rich soil, and about five Beans planted in each pot. Cover the Beans about an inch deep, and earth up when the plants are up and have made some growth. The Newington Wonder, although small, is a very useful Bean for early forcing; if well fed with liquid manure, and if all Beans are picked off when fit for use, it will continue bearing for a long time. Onions which have been taken up should now be taken under cover and stowed thinly in a dry room or on shelves; the larger should be tied in bunches, so that they can be removed to a cooler situation in February, and thus prolong the season of use. Potatoes should still be taken up in favourable weather, but avoid putting them together in large quantities in a wet state. Cut clusters of Tomatoes, and hang them in a dry airy house—this will give them an opportunity of maturing later-set fruit.—E. HOBDAY.

THE ARBORETUM.

A STONELESS PLUM.

(*PRUNUS TENERRIMA*.)

WHENCE came this plant, and by whom obtained, we are unable to say. We believe, however, that it is but little known. A distinguishing peculiarity belonging to it is the fact that it is stoneless, *i.e.*, the kernel is not encased, as is usual with other Plums, in a hard shell. The tree itself is one of moderate growth, and bears flowers of an average size. Its fruit, which is heart-shaped, is of a deep violet colour, and covered with bloom so heavily as to give it a whitish appear-

A Stoneless Plum (*Prunus tenerrima*).

ance. It ripens in August, but is of no little value except for ornament, or, perhaps, for pre-serving.

ILL EFFECTS OF ROOT-COILING.

ATTENTION has again been directed to this evil by the failures of several Cypresses planted from four to seven years ago. The Monterey Cypress (*C. macrocarpa*) is said to die out quickly in every part of Australia within thirty miles of the coast; but there is some reason for believing that its early decease should not always be attributed to the locality. This species is but one of several which have died prematurely. The others that have been brought under our notice are *C. Goveniana*, *Lambertiana*, *horizontalis*, and *Undeana*. Examination of the roots revealed the fact of death having in every instance been occasioned by root-coiling. It may be necessary to explain that the coiling of the roots is occasioned by growing the young plants in pots, in which condition the roots go round and round, and, unless care be taken when planting out to open them up and cause them to radiate from the centre, they continue the spiral course. It will be easily understood that when these cork-screw roots swell they form a solid rope; as each strand increases in diameter it presses on its neighbour, so that, in the end, the circulation of the sap is altogether stopped, and the death of the tree ensues. It is worth notice that this effect is not experienced in the case of all kinds of Conifers; some of them appear to have the faculty of throwing out roots from the collar of the plant, and of thus rendering it, in some measure, independent of the coiled roots. There have probably been more pot-grown specimens of *Pinus insignis* planted out than of any other tree, and yet hardly a complaint has ever reached us of losses of these by root-coiling. Many specimens of the choicer *Pinus*s, *Deodars*, and other *Cedars*, have been lost through this cause, so that it will be well for planters to note carefully the species which are liable to suffer and those which are not. The great lesson to be learnt is caution in buying. When selecting Conifers at a nursery do not choose the largest plants, but prefer those which have been the shortest time in pots and which are also making free and healthy growth. Not only is no time lost by making use of the youngest plants, but the ultimate stature of the tree will be far greater than it ever can be from a root-coiled subject.—*Australasian*.

ON TRANSPLANTING TREES AND SHRUBS.

By LEWIS BAYNE.

DURING the last few years the writer has had considerable experience in this sort of work, having superintended the transplanting of a vast number of trees and shrubs at different seasons of the year, and he now begs respectfully to report the result of that experience. It may only be stated at the outset that the locus of the operations to be reported on is a few miles inland, and having a northern and western exposure.

1. This transplanting took place in the second week of April, 1868, and the lot then transplanted included two large evergreen Oaks (*Quercus Ilex*) about 15 feet high, with about the same spread of branches; eight English Yews, 7 feet high; a number of Norway Spruce of the same size, and three dozen common Laurels, 3 feet high. One of the Oaks lost all its leaves the first summer after removal, but immediately afterwards revived, while its neighbour died during the second summer, which, it may be observed, had been growing among stones, lime, and rubbish, and very little soil was attached to the roots, the roots themselves being inferior, with few fibres. Both these circumstances would, in a great measure, account for the failure. The remainder of the lot survived the operation, but with varying success—none of them making much progress the first two seasons. The Yews were least affected by the removal; the Laurels shed their leaves, but recovered the first season; and the Spruce, which almost stood still for a while, have shot up wonderfully since. The dry summers of 1868 and 1869 may account for their slow progress at first, although they were watered at planting and occasionally after. The soil, it should be mentioned, was a mixture of turf and loam about 2 feet deep, and the sub-soil was an old public road, properly loosened; the new position was moderately sheltered.

2. Lot 2 consisted of some four score Spruce and a few Oaks, which were transplanted on the 11th and 15th January, 1869; although the new position was within a hundred yards of the first lot, the other attendant circumstances differ considerably. The soil was a dry loam, well trenched-ploughed, but the position was more exposed, while the plants were removed from a well sheltered position. This, together with having to contend with two dry seasons, caused the death of about 5 per cent., while the survivors have hitherto made but slow progress.

3. On the 20th of March of the same year, a removal was made of a number of common Laurels, evergreen Oaks, and common Hollies, all from 5 to 5 feet high, from a shrubbery moderately sheltered, to a very exposed situation round a newly-built lodge. The new soil was a heavy loam resting on clay bottom, and which had been well trenched to a depth of 2½ feet before planting. All the Laurels and evergreen Oaks were pruned previous to planting, but not the Hollies; the ground being moist, no watering was thought necessary. The common Laurels lost a number of their leaves, and many of the shoots of the previous year's growth died, but they have all been growing well ever since the first year after planting, and now have the appearance of being in a healthy state. About one-half of the evergreen Oaks died down to the ground the first year, but have made good shoots from the stools. The Hollies all grew, but made small progress the first year; the slow growth in this instance may be accounted for by the dryness of the two following seasons, and the exposure of the situation.

4. The next transplantation numbered about twenty English Oaks, 9 feet high, and the same number of Norway Spruce and *Pinus austriaca* from 4 to 6 feet high, with a few Birch and other deciduous trees from 6 to 10 feet high. The new soil was a heavy loam resting on clay, and trenched 2 feet deep before planting. The English Oaks, Spruce, and Austrian Pines were removed from a young plantation and carted a distance of about two miles, and neither had been previously prepared for removal. The soil on which they grew was a poor loam resting on a cold clay, and the situation was very exposed, modified, of course, by the shelter of the other trees in the plantation. The new locality was also exposed. All the other plants were brought from a public nursery by rail, and afterwards carted about 4 miles. No pruning was done in either case. As regards the Oaks, the result was that one-fourth of them died the first year, and the remainder, although keeping in life, made little progress during the first two years. Only three of the Spruce and Pines died, but the others made slow growths the first year, especially the Spruce, the *Pinus austriaca* recovering, and feeling the removal less than the Spruce. The failure and slow growth of the Oaks may be accounted for by the want of pruning and preparing for removal, and the want of shelter. The want of shelter also damaged the Spruce; as a rule, they never make much progress for a year or two after removal, when taken from the shelter of a plantation; of the Birch and other plants, one-sixth died, a result not altogether unexpected, in consequence of their having no balls of earth adhering to their roots.

5. Again, on the 31st May and 1st June of the same year the removal was effected of a number of trees consisting of three *Pinus Cembra*, 9 to 10 feet high; four *Araneaia imbricata*, 5 to 6 feet high; three *Arbor-vitæ*, about 12 feet high; and a few Junipers, 5 to 6 feet high; all were growing within the shelter of and close to a high wall, and were only removed about 60 yards into the open ground, so as they might get hardened, and prepare roots for transplanting elsewhere. They were all properly watered when re-planted, and twice a week for some time after; when shifted they had good balls of earth adhering to their roots, and they have since grown well; indeed, in the course of making alterations the following year, the *Pinus Cembra* were again removed (on the 2nd June, 1870), and it was then found that they had made great root growth since their previous removal.

6. On the 28th of June, 1870, a transplantation was made of about fifty small variegated Hollies, some standard Hollies, and upright Yews,

Junipers, and *Mahonia aquifolia*, all having balls of earth with the exception of the Hollies and Mahonias, which, however, had first-class roots. All were re-planted in well-prepared soil, wherein bedding plants had been previously grown, and were copiously watered. Not one death took place in the whole lot, nor did any show signs of feeling the removal. From the above date to 7th July three were also removed, and carted a distance of three miles, a large quantity of Portugal Laurels, common Laurels, Hollies, and *Aucuba japonica*, and planted in a more exposed situation than from whence they were taken. All have grown, with the exception of four common Laurels, which died down to the ground, but have again thrown out shoots from the bottom. The other common Laurels lost many of their leaves the first season, but soon regained their foliage, and are now growing vigorously. The Portugal Laurels never lost their leaves, but made slow growths until the year 1872, but they are now thriving well. All were watered when planted, and occasionally afterwards.

7. The preparation for, and formation of, a new shrubbery during the spring of 1871, afforded an opportunity for transplanting on a large scale. Between the 11th April and 2nd May, there were removed and re-planted twenty English Yews from 7 to 10 feet high, and very bushy, about eighty Portugal Laurels from 3 to 8 feet high, about 150 common Laurels from 3 to 6 feet high, about twenty Hollies of the same size, one *Arbutus* about 6 feet high, and a few other plants. The result was that only two plants (Portugal Laurels) of the whole lot died, and these, it may be noted, had not good roots, nor soil adhering to them when planted. A few of the common Laurels lost some of their leaves, and many of the young top shoots died down from 6 to 9 inches from the top, but on being pruned commenced growing at once, and had made good growths by the autumn; probably had these been pruned when planted they would never have shown signs of feeling the removal. All were well watered when planted, and copiously watered and syringed with a hose from a heavy supply of water several times a week for some time after; success in this case may be attributed to the soil being previously well prepared, and the abundant waterings they received both to their roots and leaves. They had, besides, been carefully planted, and having only been removed about 100 yards from their original position, plenty of soil attached to their roots, which were not long exposed to the atmosphere. Between the 18th May and 3rd June, in the same shrubbery, there were re-planted a number of Portugal Laurels 4 to 6 feet high, and very bushy, English and Irish Yews 9 feet high, *Arbutus* 7 feet high, and *Aucuba japonica* 3 feet high; all underwent the same treatment as those above alluded to, and all have grown well. In connection with this it may be mentioned, that on some of those (re-planted on the 11th to 18th April) being again removed, from the 4th to 12th September, they were found to have made good root growth; on this occasion they were also well watered. The Laurels were not injuriously affected by the change, but two of the English Yews faded and drooped a little for some time after planting.

8. On the 4th and 5th December of the same year (1871), a change of place was tried with two *Cedrus Deodara* about 18 feet high, and one evergreen Oak about the same height. The soil was a cold clay, with which was mixed on transplantation a fair quantity of good black loam. The *Cedrus Deodara* both look as well as when they were planted; but the evergreen Oak died at once, never having shown any signs of life. The failure of the Oak was perhaps attributable to its want of roots. Previous to removal it had been growing on a cold wet clay sub-soil, and when dug up for transplantation it was found that such of the roots as had penetrated the clay under the surface soil were entirely rotten and full of water. It may also be mentioned, that although the tree had stood for thirty years in the same place, its roots had only spread to about 4 feet from the trunk and gone about 15 inches deep.

9. Another removal was made within the enclosure immediately above referred to, during the last week of January, 1873, when about fifty common Laurels 3 to 6 feet high, and about eighty Scotch Firs 4 to 6 feet high, were transplanted. The ground was previously well trenched, and there were added a few loads of good soil. Only two or three of the whole lot died, but many of the Scotch Firs have made little growth, which is attributable, probably, to the cold soil and the effects of the very wet season on such ground. Again, between the middle to the end of March there were removed from the same plantation about 300 Scotch Firs, similar to those removed in January, but to a more exposed and drier position, and much better soil, which was well trenched 2 feet deep to receive them. Of the whole number only five have died, some made good shoots, while others made very small ones, which might have arisen from the latter not having had such good roots or such large balls of earth when removed. In this case the wet season has been favourable to the growth of the trees, as the soil, being of a dry loamy nature, did not hold the same as the clay in the previous case.

10. On the 29th March, 1872, a Yew hedge about 5 feet high was planted, containing two dozen plants, of these only five are now living, all the others having shown signs of perishing immediately after planting. The reason of the failure is easily understood, however. The plants were got from a public nursery, where they had been planted and grown as a hedge for a number of years, never having been removed, but regularly switched, so as to form an upright fence. They were, of course, growing close together, and had no room to make good roots. In fact, the roots were interwoven with each other, and it was consequently impossible to secure a good ball of earth with each plant. Besides, they were not considered nor sold as first-class plants, but at a cheap rate, and were purchased and tried merely as an experiment, as to the success of which no very sanguine hopes were entertained, more particularly as they were planted in the shade of, and partly under, a very old and large English

Yew, whose roots extended a long way and appropriated all the moisture. At the end of said hedge, however, a week previously, five English Yews about 7 feet high, which had been removed from a neighbouring plantation, were planted, and all have grown and appear healthy. This shows the advantage of good balls of earth adhering to the plants, and the keeping the roots only a short time exposed to the atmosphere.

It has been ascertained that transplantation does not always check the growth of a tree, but, on the contrary, benefits it in no small degree. In proof of this the following may be noted:—A group of *Wellingtonia gigantea*, from 6 to 10 feet high, growing in the pleasure-grounds, were, with one exception, found to be in a far more prosperous condition. The exception, which had over-topped the others by several feet, was growing on the site of an old sunk fence, levelled and filled up, the ground being loose, and, as it were, prepared before planting. Its less fortunate neighbours had clay for a sub-soil, to which their roots had penetrated, and on the 23rd and 24th September, 1870, an effort was made to invigorate them. The trees were accordingly dug up, a quantity of clay all round and under their base removed, and replaced with good soil, mixing the clay and soil to some extent, and placing brickbats, &c., in the bottom for drainage. In their new position they were raised about a foot above the natural level of the surrounding ground. The trees were well watered when re-planted, and are all now thriving again. A *Wellingtonia gigantea*, about 12 feet high, had to be removed out of the line of a proposed carriage-drive, and it was carried to a new situation on 3rd October, 1870. The result was equally successful. In the year 1871 it produced cones for the first time, and next year the cones upon it were more numerous. At the same time, a difficult removal (from a distance of several miles) was effected of a *Cedrus Deodara*, 15 feet high, with large spreading branches, and a considerable number of Portugal Laurels, all of which, notwithstanding various disadvantages, in the shape of rough usage, exposed position, &c., have stood the change, and are thriving.

In the foregoing paper the writer has noted down what has come within his own personal observation only, and it remains for him now to make a few remarks, suggested by his own experience, as to the trees best fitted for transplantation, the season of the year best suited for the work, and the treatment of the tree before and after transplantation—although in actual practice it is not always possible to carry out one's ideas. The first thing to be done is to select a suitable plant for the object in view. It should be well grown, and have a fair supply of branches; and it ought, if possible, to be taken from a more exposed and less favourable situation than the one to which it is to be removed. To prepare it for removal, a trench should be dug round it in the autumn or spring of the year previous to removal, about 2 feet wide and deep enough to get well under the roots, the distance from the stem varying (3 or more feet), according to the size of the tree, and re-filled with good loam or a mixture of decayed turf or leaf mould. Judicious pruning of the wider-spreading branches should also be had recourse to, especially if the tree or shrub is of a straggling habit of growth; generally speaking, those having straggling branches have long running roots, and which, on removal, are, to a certain extent, necessarily shortened. The more there is cut off the roots, accordingly, the more pruning is required so as to balance the tree, as well as to limit the demand for nourishment, the means of supplying which has been more or less reduced by the cutting of the roots. Pruning is most especially necessary in the case of large forest trees, which, as a rule, have less fibrous and more spread roots than shrubs. The place to which the removal is to be made should invariably be prepared and loosened by trenching or digging, and well drained; and if the soil be poor or a stiff clay, a mixture of good loam or decayed turf and leaf mould, would go far to secure the success of the operation and after benefit of the plants. It is also very advisable to have the new situation raised a little above the surrounding level of the ground, so that the roots may be dry and warm, and have an opportunity of spreading in search of nourishment in the surface soil. They should be watered abundantly when re-planted, and afterwards if necessary. It should be kept in view that it is all important to preserve the roots from accident in the act of transportation. Further, they ought, as far as possible, to be protected from the sun and wind, and action of the atmosphere, by the use of matting or otherwise. With reference to the size of trees to be transplanted, it may be observed, that although large trees, say upwards of 18 feet high, may be removed and re-planted, it is seldom advisable to do so. There is always greater risk of the work not being performed successfully while (assuming that they survive transplantation) they often continue long at a standstill without making visible progress, and have a sickly appearance for years to come. This would not be the case with trees of smaller size. They would take to the new soil rapidly, look lively, and, ere long, outstrip their larger neighbours transplanted at the same time as themselves. Besides this, the trouble and cost of removing the smaller trees will be much less than in case of the large; while, with the latter the risk of total failures is proportionally greater. As to the most favourable time for the planting of deciduous trees and shrubs, the writer would recommend from the middle of October (just when they begin to shed their leaves) to the last week in November; and from the middle of February till the last week in March, when the trees begin to break bud. The operation may, however, be performed successfully from October to March inclusive, should the weather remain mild and open. Evergreens may be safely removed all the year round, but the preferable time is from the middle of September to the middle of October. Autumn planting saves the expense of watering, which cannot safely be dispensed with in summer planting; and this expense becomes considerable when the plants are numerous and of large size, and the water a distance to carry. Other good times for removing

evergreens are the beginning of April, and from the last week in May till the second week in June, but they then require copious waterings to ensure their success. In the case of lawns and other dressed ground, mid-summer transplanting has the advantage of not cutting up and destroying the ground in the performance of the operations, the ground at that time being generally firmer than in the months of September and October. It will be obvious that while the ground is firm the work of removal must be more easily performed. After transplanting, it is necessary that the trees should be well secured against prevailing winds. To effect this, various methods are employed; one of which is by driving three stakes into the ground at angles, and tying or mooring the trees with strand and cable wire, or pitch cord, using hay or matting, or other soft substance, to keep the rope from destroying the bark. This, in the writer's opinion, is the most efficient mode of protecting large trees against wind. Trees of smaller size may be secured by driving two cross stakes well into the ground at proper distances from the stem, so as not to injure the roots, and then tying the plants between them. Another method is by stakes, and cross rails 2 or 3 feet from the ground, according to circumstances; or close upon the roots under the ground, when the plants have large balls. This last way avoids the unsightly appearance of the stakes and rails in parks and ornamental grounds. Almost nothing requires to be said about the methods of removing the trees from the old to the new situation, as they vary according to the peculiar circumstances of each case, the size of the tree, the nature of the road, the distance to be carried, &c. It may be mentioned, however, that all the removals spoken of in this paper were effected by means of a large low four-wheeled truck or wagon, without sides, for the heavy trees, and one of smaller size for the lighter ones. To the former could be attached two or more horses, and the latter was available for horses or workmen merely. The trees were raised upon these by means of planks and rollers, and in the case of the smaller plants by strong hand-barrows. These were found quite sufficient for the purpose.—*Highland Society's Transactions.*

THE OLD SURPRISE.

Now what hath entered my loved woods,
And touched their green with sudden change?
What is this last of Nature's moods
That makes the roadsides look so strange?

Who blanched my Thistle's blushing face,
And gave the winds her silver hair?
Set Golden-rod within her place,
And scattered Asters everywhere?

Who splashed with red the Sumach hedge—
The Sassafraz with purple stain;
Gave Ivy-leaves a ruby edge,
And painted all their stems again?

Lo! the change reaches high and wide,
Hath toned the sky to softer blue;
Hath crept along the river side,
And trod the valleys through and through;

Discoloured every Hazel copse,
And stricken all the pasture lands;
Flung veils across the mountain tops,
And bound their feet with yellow bands.

Is, then, September come so soon?
Full time doth summer ne'er abide?
While yet it seems but summer's noon,
We're floating down the autumn tide.

Mahogany Trees in India.—It is Dr. King's opinion that no difficulty is likely to be found in "planting Mahogany on a large scale in districts of Lower Bengal." Of this cultivation Dr. King says:—"The Mahogany plants were raised from seeds received from Honduras and Jamaica. There are, as Government is aware, a good many old Mahogany trees about Calcutta. These, however, rarely yield seed, and our supplies are mostly derived from the West Indies and Honduras. I am strongly of opinion that, if it can be got in no other way, it would be worth while to hire a man specially to collect and transmit seed to India. It has been abundantly proved that the tree will thrive in most parts of Bengal, and that the Indian-grown timber is valuable. There are fine trees of it also in the gardens at Saharunpore and Madras, and I have no doubt that it will grow admirably in almost any part of India in situations free from frost, and where a little moisture can be secured in very dry weather. I see no difficulty in getting up plantations of it on a large scale and at a moderate cost. The Mahoganies here which were spared by the Cyclone are by far the finest trees of any sort the garden contains. They were planted about eighty years ago, and at present, at a height of 6 feet from the ground, their girth runs from 8 to 11½ feet. Now the average girth of Teak at ninety years of age is only about 6½ feet and that of Sál is less."

THE GARDEN.

"This is an art

Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

THE BRASSICA TRIBE IN LONDON MARKET GARDENS.

THE CABBAGE.—What is called the Enfield Cabbage is that which is used in the market-gardens about London. It is one of the oldest in cultivation and one of the best, and as growers of it generally save their own seed, they take particular care that their plants of it are not crossed with other sorts. The sowing for the principal crop of this Cabbage is generally made on St. James's Day, the 25th of July, or some time between that and the middle of August, and if the sowing be made on poor ground so much the better, as in that case the plants come up stocky and hardy, and stand the winter well, whereas, if made on rich ground, a soft rank growth is produced, which is much more easily injured. This sowing is, as a rule, made in 4 feet wide beds, a width found to be convenient for weeding and hoeing amongst the plants. By the time the latter are sufficiently strong to be transplanted the Potato or Onion ground is ready for the reception of a first batch of them, and on that cleared of Celery, French Beans, or Vegetable Marrows, another plantation is generally made. Every empty space under fruit trees or elsewhere is also planted with Cabbages. In planting, the ground is lined off into rows, 35 inches apart, and in these the plants are put in 15 inches asunder. Between every two rows first planted another is now put in with less care, thus making the plants stand 15 inches apart each way. Early in spring every alternate line of plants, and also every other plant in the lines or rows left, are lifted and sold as Coleworts, *i.e.*, young open Cabbages, a state in which they are preferred by many to such as are hearted. This allows the permanent crop plenty of room to come to maturity. With a view to subsequent plantations, which are made all through the winter wherever ground is vacant, the young plants in seed-beds are removed and pricked out into others a little further apart, in order to keep them in good condition for planting out as long as possible. In this way, indeed, many of the plants are kept till spring, when they are transplanted to succeed those planted out in autumn, and to come in before the produce of the spring sowings, made late in February or early in March, to furnish Cabbages from June to August. The plants from this sowing are put out in rows 2 or 2½ feet apart, and in the intervening spaces are put lines of Lettuces, a plant of which is also set between every Cabbage in the row. If thought necessary, another sowing is made in the end of March, or in April; and sometimes a bed is sown in May, when what are called Rosette Coleworts are sown. As the latter are, however, chiefly grown for late autumn and winter supplies, Cabbages are seldom sown after March. Moreover, when Peas, French Beans, and Vegetable Marrows are in, there is little demand for Cabbages. Red Cabbages are sown in March or on St. James's Day, and the plants are put out in rows from 3½ to 4 feet apart, and the plants stand about 3 feet asunder in the rows. As this crop stands until the heads are large and solid, a piece of rich land is devoted to it, and intercropped with Potatoes, ordinary Cabbages, Lettuces, French Beans, or other vegetables of that kind. The produce of the July sowing is generally considered better than that of spring.

COLEWORTS.—These are simply unhearted Cabbages, pulled for market when about half-grown; any small variety of Cabbage may, therefore, be grown for this purpose. Some kinds, however, better deserve the name of Coleworts than others, and these are often left until they heart. Among them are the Rosette, a valuable kind, usually sown in May for use between October and Christmas; and Cock's Hardy Green Colewort, a desirable sort for winter use, as it is hardier than the Rosette. Another sort, called Blue Colewort, is largely grown by some market gardeners; but it is a kind which is

apt to "run," and is generally grown for the November crop. For spring Coleworts, only the thinnings of the Fulham Cabbage are used. The Rosette is, perhaps, the greatest favourite in the market, its beautiful white heads, when bunched, having an attractive appearance; but, as regards quality, nobody would eat the Rosette who could get Cock's Hardy Green—*i.e.*, if they were acquainted with the respective flavours of the two varieties. A sowing of the Rosette is usually made in May, in beds in an open piece of ground, and, when up, the young plants are thinned with small hoes. The strongest plants are first selected for transplanting, and are put in chiefly as catch crops between other vegetables. As soon as fruit bushes have been cleared of their crops two rows of Coleworts are planted between them; they are also planted under fruit trees, no matter how large the trees may be, and also between rows of Moss Roses. The space between Celery ridges is likewise generally planted with Coleworts, as is also that between Asparagus ridges, the edges of which, too, are often cropped with Coleworts. Between the rows of French and Runner Beans, and late Savoys, this Colewort is likewise planted, and, in fact, like Lettuces, it is planted in every empty space where there is a probability of its growing to a useful size. Whole fields, too, are sometimes cropped with it, and are cleared in good time for winter Radishes. Cock's Hardy Green Colewort more resembles an ordinary Cabbage than the Rosette, and, being hardier, is sown a month or six weeks later, so as to form a succession to that sort.

BROCCOLI.—The chief supplies of white Broccoli brought to the London markets between November and April are grown in the south and west of England, but principally about Portsmouth and Penzance, in Cornwall. From these sources Broccoli is obtained in large quantities, and of excellent quality. In the market gardens about London the purple Sprouting, the Walcheren, Snow's Winter White, and Cock's Late White, are the kinds chiefly grown. The first sowing of Sprouting Broccoli is usually made in April on a rich piece of ground, either in beds or broadcast. When the young plants appear above ground they are first hand-weeded, and afterwards thinned by means of narrow hoes. As soon as they are strong enough for transplanting they are planted in rows about two feet apart under fruit trees, or in some other shady situation, this crop, owing to its succeeding tolerably well in shade, seldom being afforded an open quarter. When planted between rows of fruit bushes, two lines are inserted in the intervals between every two rows; but if two drills of Potatoes occupy this space, then only one line of Broccoli is planted, and that between the two drills of Potatoes. Should the whole space under an orchard be planted with Potatoes in drills about 2½ feet apart, in that case, as soon as these are earthed up, Broccoli is planted between the rows without the soil being loosened. The Potatoes ripen before the Broccoli can injure them much, and when the Potatoes are removed the Broccoli has the whole space to itself. The trees lose their leaves in October; therefore the Broccoli, having the benefit of increased light, becomes invigorated, and during that month and November begins to afford a good supply of sprouts, which are not all gathered at once, even from the same plant, but at intervals, as they become fit for use. The soil for Broccoli should be rich, otherwise the plants are liable to club, and if the ground be too dry, premature sprouting, before there is a market for the produce, is the result. Another sowing is generally made in the middle of May; indeed, from this sowing the principal winter crop is obtained, and more plants are raised than are absolutely required, as all clubbed and weakly ones are discarded at planting time. Sometimes the time of year, when ground will be vacant, materially influences the season for sowing; for it is an important matter to have the young plants in a healthy stocky condition at planting time. If sown, therefore, so early as to have to be kept in the seed-bed until they have become "drawn," they sprout sooner than required, and before there is any demand for them. For late sprouts a sowing is made about the end of June or first fortnight in July, the produce of the first sowing being transplanted. From this sowing sprouts will be obtained in the following spring in March and April, and after they are removed the ground will be in good condition for receiving Wallflowers. WILLIAM FALCONER.

NOTES OF THE WEEK.

— A NEW garden has been formed at St. Petersburg, to be devoted to illustrate how native plants may be effectually used in garden embellishment. It would be no very difficult work to form a charming garden with our own wild flowers, and shrubs, and trees, and we commend the effort to those who wish to establish a novel feature in their garden.

— At the Aberdeen Fungi show, a meeting of botanists was held, when it was agreed to form a Scottish Cryptogamic Society, which, by an annual exhibition held in the larger cities by rotation, and by other means, would endeavour to promote a more complete knowledge of Cryptogamic plants. It is intended to hold the exhibition next year at Perth.

— A HEAVY storm has passed over Belgium, clearing hardy fruit trees in many instances of their crops, and doing other damage. It has been observed, however, that some sorts of fruit have withstood the storm better than others, and to ascertain what varieties do and what do not retain their fruit during stormy weather may be a matter worthy of more attention than it has hitherto received.

— In a paper "On the Periodicity of the Rainfall in the United States in Relation to the Periodicity of the Solar Spots," by Prof. John Brocklesby, the author concludes from his investigations, that there is a connection existing between rainfalls and variations in the sun-spot area; the rainfall rising above the mean when the sun-spot area is in excess and falling below it when it is deficient.

— In "Notes on Tree Growth," read by Prof. Asa Gray, before the American Association for the Advancement of Science, the author says, whether the trunk of a tree increases in length, in the parts once formed, is still an open question in the popular mind. From careful observations made by Prof. Gray and many others, the conclusion is, that the trunks of trees do not grow in length, in that sense.

— THE consumption of Osiers for various purposes, in England especially, is very great. Besides her own production, this country, *Nature* informs us, imports more than 5,000 tons, valued at about £40,000. About 300 varieties of Osiers are known, the most important beds being situated near Nottingham; the home produce being insufficient to meet the demands, great attention is being paid to the cultivation of beds in Australia, and a considerable quantity is yearly produced in that country.

— In a paper "On the Distribution of American Woodlands," read by Prof. Wm. H. Brewer, of New Haven, before the American Association for the Advancement of Science, the author stated that the flora of the United States is believed to contain over 800 woody species, and over 300 trees. Of these trees, about 250 species are somewhere tolerably abundant; about 120 species grow to a fairly large size; twenty attain the height of 100 feet; twelve a height sometimes of over 200 feet, and a few—perhaps five or six—a height of 300 feet.

— THE most elegant plant now in the flower-gardens of the London district is the old and well-known *Acacia lophantha*, a plant for which of late years a new use has been found. It is very effectively used in adding a Fern-like grace to flower-beds, and sometimes in masses, with "carpet" plants beneath. At Heckfield, Mr. Wildsmith uses it as a vase plant, and with a charming effect in softening the mass of *Pelargoniums* from which each plant springs; the plants thus used are seedlings of the current year. It is also one of the most useful of window plants, showing its delicate frond-like leaves throughout the winter in the dry air of any living room.

— THE first Fungus exhibition held in Scotland was opened the other day in Aberdeen. The idea of the exhibition was first suggested by the Rev. Mr. Ferguson, of New Pittslo, in the *Scottish Naturalist* for April. The suggestion was readily taken up by Fungologists and men of science, and the result was an exhibition which those entitled to speak with authority say was never equalled in this country. The specimens numbered about 7,000. Almost every county in Scotland made large contributions, while England and Wales sent a number of exhibits. In fact, almost every Fungologist in Britain contributed specimens.

— SOME of our readers may like to know that on Wednesday next an exhibition of edible and poisonous Fungi will be held at South Kensington, where prizes amounting to £28 will be competed for in the following classes, viz.:—Class 1. Collection of Fungi arranged according to their botanical affinities. Neat arrangement and correct nomenclature will be taken into account in awarding the prizes. The edible and poisonous species are to be so marked on their respective labels; the edible species being named on white labels, the poisonous on red labels, the rest on yellow labels. Prizes £5, £3, £2. Class 2. Collection of Edible Fungi. These should be shown, when possible, in juxtaposition with specimens of similar but noxious species. Prizes £3, £2, £1. Class 3. Collection of New or

Rare Fungi. Prizes £3, £2, £1. Class 4. Cultivated Edible Fungi. This class is intended for species likely to be useful as esculents, but which are not now known in the cultivated state. Prizes £3, £2, £1.

— THE common Hemp is used with very good results in the flower gardens round London this year. It is particularly effective at Battersea, where it attains a height of more than 10 feet.

— At a late meeting of the Paris Academy of Sciences, Dr. Hofmann announced that his two students, MM. Tiemann and Haarmann, who had obtained vanilline (the aromatic principle of the Vanilla Bean) from Pine sap, propose to manufacture this substance on a large scale. The sap of a tree of medium height gives vanilline to the value of 100 francs, and the wood is not injured by the extraction of the sap. This will be the second vegetable product manufactured by purely chemical methods.

— THE fine days we have recently enjoyed have so checked the work of autumn in the London parks that the flower-gardens therein are now full of beauty. Our notices this year have, for the most part, concerned Hyde Park; but to Battersea, as usual, the palm must be given, and Victoria Park is also very attractive. It is a most favourable time then for visiting these gardens and making notes of recent introductions and arrangements. We may add that the Crystal Palace gardens are by many thought to be better and brighter than ever this year so far as bedding-out is concerned. We have recently alluded to the manner in which these once noble gardens have been violated by the builder.

— THE current number of the *Botanical Magazine* contains coloured plates of the following new and rare plants, viz., *Tacca artocarpifolia*, an herbaceous stove plant closely resembling *T. pinnatifida*, and differing from the commonly cultivated *T. cristata*, more particularly in having pinnate foliage. *Pogonia discolor*, a charming addition to variegated Orchids, having deep green leaves marked with radiating orange-yellow lines, and closely set with yellow hairs. *Lilium (avenaceum) maculatum*, a showy orange-yellow species, spotted with brown. *Scorzonera undulata*, a rosy-flowered composite of slender habit. *Citrus Aurantium* var *japonicum*, the Kumquat figured and described in *THE GARDEN*, p. 501, Vol. V.

— A NOVEL and altogether excellent idea, says the *Gardeners' Record*, was started by the committee of the recent International Show, at Belfast, when they offered prizes for the best cropped Vioeries in the province of Ulster, and we trust the example thus set will be imitated by the Royal Horticultural and other societies throughout the country. Competition of that class would tend to do more for the improved cultivation of the Vine than the most lucrative prizes that could be offered at a flower or fruit show, and would be productive of more real benefit to the owners of gardens. We trust the committee of the Royal Horticultural Society will give the matter some consideration when arranging their schedule for next year, and that liberal prizes will be offered for the best house of Grapes in the province of Leinster, if they do not deem it judicious to open the competition to the whole of Ireland.

— MR. MEEHAN has been at work again on the origin of species. After adducing many instances in support of the theory that new forms are often generated by "leaps," Mr. Meehan concludes with the following propositions:—1. Morphological changes in individual plants are not always by gradual modifications. 2. Variations from specific forms follow the same law. 3. Variations are often sudden and also of such decided character as to seem generic. 4. These sudden formations perpetuate themselves similarly in all respects to forms springing from gradual modifications. 5. Variations of similar character occur in widely separated localities. 6. Variations occur in communities of plants simultaneously by causes affecting nutrition, and perhaps by other causes. Mr. Meehan argues from these premises that new and widely distinct species may be suddenly evolved from pre-existing forms without the intervention of connecting links.

— THE New Zealand Flax (*Phormium tenax*) is being successfully cultivated in St. Helena. Hitherto no very great attention has been paid to the cultivation of this plant, and the natural supplies obtained in New Zealand are insufficient for the demands of commerce. This is not to be regretted, for careful cultivation cannot fail to improve the fibre, and the best kinds alone will be worth the trouble of proper rearing. Steps are, however, being taken to cultivate this plant in New Zealand and in other countries. In the Azores, at St. Helena, in Algiers, and the South of France, it thrives well, and has been easily naturalised. The fibre is principally used for making ropes and paper, for the caulking of vessels, for stuffing mattresses, and for coarse textile fabrics. We should like to learn the value of fibre grown in the south of Ireland and England as compared with that grown in warmer countries. The plant grows well in Cork and Devon, either in or out of the water.

GUERNSEY AND BELLADONNA LILIES.

Among the plants popularly known as Lilies there are few more beautiful than those we here figure. The Belladonna Lily (*Amaryllis Belladonna*), is a native of the Cape of Good Hope, and has long been an inmate of our gardens, although its culture has never been so general as it deserves. Planted on the warm narrow borders in front of plant houses or pits, it forms a beautiful object late in the autumn; or, plants of this

The Belladonna Lily.

and *Helleborus niger*, the Christmas Rose, may be planted alternately, and then the latter will continue the supply of bloom into December or January. A deep rich moist border suits it best, and in suitable situations the flower-scapes are often 18 inches in height, and bear as many as eight or nine blooms each. The colour of the flower is white, delicately shaded with soft rose, making the plant very beautiful either as a border flower or for drawing-room vases. The Guernsey Lily (*Nerine sarniensis*) is rather more tender, but does well treated as a pot plant; and, as it flowers freely during September and October, it comes in very usefully for conservatory and greenhouse decoration, or even for the ornamentation of

The Guernsey Lily.

windows and rooms. Bulbs of both plants are largely imported in August, and flower in two or three weeks after they are potted. The bulbs only cost a few pence each, and can be selected when the flower-spikes are showing, so that their flowering is reduced to an actual certainty. Pot them in any light rich soil, and place them in a cold frame or pit until their flowers expand, after which they may be removed indoors to bloom. Thus treated, they seldom fail, and both plants deserve to be grown in quantity in every collection where hardy or half-hardy flowering bulbs are appreciated. B.

WINTER AND SPRING FLOWERS IN COVENT GARDEN.

A WONDERFUL place is Covent Garden at all times of the year, but more especially during the winter and spring months. Early in December Christmas Roses—so named from the resemblance their flowers have to the wild Roses of our hedges—begin to make their appearance, both in the shape of cut flowers and in pots. Then comes the winter Aconite, which is sold in little tufts wrapped in damp Moss; but not so much so as to conceal its fresh green leaves and bright yellow flowers. Next appear Snowdrops done up in a similar manner. These are succeeded by Crocuses, Hyacinths, Tulips, Daffodils, Squills, and hosts of similar early flowering bulbous plants, either lifted from the open ground just as they come into bloom, or in the form of cut flowers, and the fine condition to which they are brought, especially those in pots, is quite surprising. They are potted in October and November, and are buried in ashes or cocoa-unt fibre for some two months, so as to get the roots in advance of the tops, when they are gradually inured to light, and forced into flower slowly, so as to induce them to produce good fresh green leaves along with the blooms. As soon as they show their flower-buds extra ventilation is given, and the plants being near the glass, dwarf sturdy growth is thus obtained. In the case of Van Thol Tulips, the kind usually grown for market, they are thickly packed in shallow boxes, in which they are left until they come into flower, when they are potted four and five together in 6-inch pots. In the centre of each pot is sometimes put a small Fern, a graceful combination which, when the Tulips are in bloom, is very effective. Perhaps the greatest favourite of all, however, is the Lily of the Valley, which when loaded with little "green-tipped lamps of white," is undeniably a queen among flowers. This is treated in the same manner as the plants just named. It should, however, be potted as early as August or September; indeed, the earlier it is potted the better, so as to have good established plants before winter sets in. At potting time roots with plump solid crowns are selected, and in as large masses as can be got into the pots. Should they happen to bloom irregularly, as soon as this can be perceived, they are turned out of the pots, divided, and equalised, the weakly roots being potted together and utilised for cut bloom. Scarcely has the market been made gay by means of bulbous plants, than bunches of double-flowering Daisies, common wood Primroses, and garden Polyanthus, make their appearance, together with Anemones, Hearts-ease, Aubrietias, Violets, the early white Arabis, dwarf Phloxes, Wallflowers, and multitudes of other early blooming plants, all welcome indications that "summer is coming, and that cold winter is away." These plants, which have been lifted with balls of earth attached to their roots, are packed closely together in shallow boxes, and are sold singly or by the boxful, as may be required. For such roots as those of Canterbury Bells, Hollyhocks, Larkspurs, Monkshood, Peonies, and similar hardy herbaceous plants, there is also a brisk trade, as well as for Stocks, Asters, and Balsams, young plants of which are exposed for sale in flat boxes in abundance. Sweet Peas, Nasturtiums, and Tropaeolums, are sold when about 2 or 3 inches high, in 6-inch pots. Among plants suitable for wall decoration, the Virginian Creeper is a great favourite, as are also Jessamines and Irish Ivies, all plants that do well in towns. Foremost among window plants stands the Creeping Jenny, a favourite with everybody, and though a native plant, grown largely in gardens to supply the London trade. For fairy Roses and for Periwinkles there is also a large demand, as well as for Ferns, of which basketsful stand about everywhere, fresh and green, reminding one of the sweet spots far away from noise and bustle, from which they have been rudely torn. Go, too, to Covent Garden at any time, and it will be found to contain evergreens in profusion, in pots, more especially Aucubas, or Spotted-leaved Laurel, as it is sometimes called, a shrub much sought after for suburban gardens, and one which withstands smoke better than almost any other. Q.

A Japanese Nursery.—Surrounding the temple at Asacksa are extensive grounds, in which are included various shews. The most interesting part to me was that portion occupied by a florist's establishment. Here you find everything kept in the neatest order. The plants are arranged on elevated stages, shaded with rolls of fine Bamboo laced together, forming open mats, which can be rolled up when desired. They are much superior to a framework of lath, sometimes used by us for sheltering plants from the sun. The principal stock of plants consists of those most suited to Japanese tastes, viz., dwarfed Pines and Retinosporas, Sago Palms, variegated Podocarpus, Aucubas, Selaginellas, &c., many of which are sold at what we would consider very high prices. I was surprised to find growing here three distinct varieties of Verbenas, which I was not aware had

been introduced; also *Jasminum grandiflorum*, and a species of *Franciscea*. The grounds contained several species of trees unknown to me, which I would have purchased if I could have obtained small specimens. A pond full of scarlet *Nelumbiums*, the flowers standing on tall foot-stalks above the foliage, like immense Tulips, had a very fine effect. The Japanese gardeners cultivate a number of varieties of them having double flowers, and with various marking and shades of colour, some of which I hope to be fortunate enough to send home alive. The scarlet *Clerodendron* seemed to be a favourite, and large plants of it, grown in ornamental porcelain pots, made a fine show. The Japanese do not entertain our objections to growing plants in glazed pots; all their fine specimens are grown in them, and I certainly have not been able to see that they do not thrive equally as well as in any other kind.—T. Hogg.

Wood Sorrels (Oxalis).—We learn from Mr. Tyerman that the beautiful little *Oxalis lobata* is now flowering finely in his garden, in Cornwall. The bright yellow flowers of *O. lobata*, which are large compared with the leaves and short stature of the whole plant, which is barely a couple of inches high, make a really pretty and pleasing feature, such as is sure to arrest the attention of the most casual observer. When planted in masses, the ground looks studded with golden stars. Mr. Tyerman suggests that this very interesting genus of plants would do much to make our gardens more interesting at this season of the year, since they are all of the easiest possible cultivation, and in dry soils perfectly hardy, or at the utmost a slight protection from heavy rains during the dormant season would make them quite secure. *O. elegans* is, as its name implies, beautifully elegant; the leaves, which are of great substance and smooth, grow 3 to 4 inches high, and the flowers rise 6 or 8 inches above the leaves, of a pleasing rich purple-lake, with dark centre. *O. Deppei* is well known, its reddish flowers being produced well above the neat foliage for several months in succession, and like the beautiful rose-pink *O. Bowiei*, would make excellent variety in the modern flower garden. *O. floribunda*, and its numerous varieties, are hardy perennials, and are almost perpetual-flowering. Where the soil and situation are at all genial, all the summer-flowering kinds will prove much more satisfactory when grown in the open borders "than as they usually are, cramped in pots;" even that weedy species, *O. lactiflora*, is much more interesting in the open ground.—*Florist*. [There are a good many other kinds quite as beautiful as those above-named, and most precious for cultivation, especially in warm soils. The yellow *O. ceruina* is as pretty growing wild as it does in Italy, as the Cowslip is where it grows well in our meadows. There is a beautiful purple-crimson kind, also naturalised in the gardens and lawns in Italy. In this country Messrs. E. G. Henderson, of the Wellington Nurseries, have the best collection of these neglected plants we know of. They are plants, however, the beauty of which cannot be fully seen when they grow in pots and small patches. This will be understood by those who have seen *O. Bowiei* in bloom in the botanic garden at Chelsea, or in Pince's Nursery at Exeter. The distant effect of a crowd of the flowers is inexpressibly charming.]

Covent Garden Market.—Writing of the insufficiency of Covent Garden Market as it now stands, the *Telegraph* asks who is the noble landlord that has been so often memorialised, petitioned, and beset with remonstrance? The noble landlord is his Grace the Duke of Bedford; and he, by a nod of his gracious head, by a stroke of his gracious pen, would set on foot an undertaking which, in a few months, would transform Covent Garden Market into a public edifice not only commodious, but splendid. He might remember that it was the passionate admiration of his ancestor, the Bedford of Charles I.'s time, for Palladian architecture, which led him on his return from Italy, to erect on the site of the old Covent Garden a series of edifices designed to rival the Piazza del Signori at Vicenza. He might remember that he, the actual head of the illustrious house of Russell, is the possessor of well-nigh boundless wealth; that he is the Lord Paramount, not only of Woburn's pleasant shades, and the wide expanse of the Bedford level, but of scores of streets and squares—of whole districts—in London town. He might remember, that among his vassals and dependents he is a great prince; that with them his word is law; and that the opportunity is before him, not only of regenerating the huge mass of brick and mortar which he owns—not only of earning some personal celebrity for himself by rebuilding Bloomsbury and Covent Garden, as the Marquises of Westminster have built Piccadilly and Belgravia—but of still further swelling the contents of his prodigious coffers, through the enhanced value of his property. Of all these things, and of many more, we might remind the Duke of Bedford, if we only knew where his Grace was to be found. Where is he? Who will organise an expedition to the South Pole in quest of the Duke of Bedford? The House of Lords is eager for his utterances. Market gardeners, seedsmen, and florists stand ready, waiting with rich offerings, like the old tributaries of the Great Mogul, with their gold mohurs in their hands. Is he the

Mogul, or the Grand Lama of Tibet, or the Veiled Prophet of Khorassan? Or is he an abstraction, a myth, an impalpable idea—a mere dædal phantom and chimera? If his Grace could only be "got at"—if the prayers of his vassals could only be made audible to him, if he could only be brought to the wholesome conviction that property has its duties as well as its rights—he might easily, expeditiously, and without risking one shilling of his enormous revenues, convert Covent Garden into a palace. At present it bears a disagreeable resemblance to a series of dust-bins and lay-stalls, littered pell-mell about the yard of a gaol.

The Royal Horticultural Society's First-class Certificates.—At the last floral meeting held at South Kensington, Mr. Fraser gave notice that he should propose, at the next meeting, on October 7th, that something be done to give First-class Certificates more weight than they hitherto have had, more especially in the case of plants that gain a First-class Certificate by a unanimous vote, and that are of superior merit. That some alteration is needed, there cannot be a doubt, and as the subject is an important one, I trust there may be a full meeting, and one at which a decision, satisfactory to all parties, may be arrived at.—EDWARD BENNETT, *Hatfield, Herts.*

Vegetables and Salads in the Paris Market Gardens.—The ground cultivated by market gardeners, in and around Paris, amounts in all to more than 3,000 acres, and the business gives employment to 9,000 persons and 1,700 horses, these being used for pumping water as well as for transport. It is said that 360,000 glazed frames, and more than 2,000,000 cloches are employed in the production of vegetables alone. The annual amount expended for manure is said to be £72,000, and the total receipts from the sale of vegetables and other productions of the market gardens to exceed half a million sterling, which, after all, does not seem a large sum, as the consumption of Paris includes a very considerable proportion of expensive early vegetables. This sum, does not, however, represent the entire consumption of Paris, as large quantities of Potatoes, Asparagus, and other vegetables are sent to the capital from all parts of the country.

Curiosities of Grafting.—We can graft the Apricot on the Plum, and the Peach on the Apricot, and the Almond on the Peach, thus producing a tree, with Plum roots and Almond leaves. The wood of the stem will consist of four distinct varieties, though formed from one continuous layer. Below the Almond wood and bark we shall have perfect Peach wood and bark, then perfect Apricot wood and bark, and at the bottom perfect Plum wood and bark. In this curious instance we see the intimate correspondence between the bark and the leaf, for, if we should remove the Almond branches, we might cause the several sorts of wood to develop buds and leafy twigs each of its own kind. Each section of the compound stem has its seat of life in the cambium layer, and the cambium of each reproduces cells of its own species out of a common nutrient fluid.—*Cultivator*.

India-rubber Trees in India.—Dr. King, in a report on the Botanic Gardens of Calcutta, says, of India-rubber, that he "brought from England in November six plants of the Para rubber tree (*Hevea brasiliensis*), which were given to him by Dr. Hooker, of Kew. Para rubber is one of the finest sorts known in commerce, and in view of the possible early exhaustion of the rubber-yielding Figs of Assam, the introduction to India of the plant producing it becomes a matter of some interest. The rubber of this country is obtained from Fig trees, most of which (at least in early life) are parasitical. These Figs begin life by establishing themselves on the tops of other trees, along the trunks of which they send their twining aerial roots, which ultimately reach the ground. In course of time the supporting trees are killed, but the Figs remain and grow, often entirely obliterating their predecessors. It is from the long aerial roots of these Figs that rubber is mostly got, and not from their branches. After a few severe tappings a Fig ceases to yield rubber from its roots. The artificial formation of India-rubber plantations on the summits of tall forest trees is impracticable on any large scale. The Para rubber tree has no such parasitic habits in early life. The white juice, which on hardening forms crude rubber, is yielded freely by all parts of the plant, which moreover promises to be one of easy propagation.

A Reform Indeed.—As soon as we have got politics settled, business reformed, and human nature elevated, I am determined to form a society for the re-formation of botanical names. Botany has been the Noah's Ark of plants. Every absurd whim of every pragmatical professor has been turned into Greek or Latin, and hung about the neck of unhappy flowers. One might as well hang a dictionary around a child's neck by way of ornament, as to impose on flowers such outrageous and outlandish names as now defend the science of botany from all approach, as a fort is defended by a line of *chevaux-de-frise*.—H. W. BECHER.

THE GARDEN IN THE HOUSE.

TABLE PALMS.

It is not an easy matter, without a series of engravings, to explain what plants are suitable, and what plants are unsuitable, for the decoration of a dinner-table. An experienced hand will be able at once to decide whether certain plants are, or are not, suitable for a certain table, if they are shown to him in the room in which they are to be used. But a plant that may be suitable for one form of dinner-table arrangement may not be suitable for another arrangement of the same objects, used for the general decoration of the table; and again, a plant that forms a part of a very pleasing arrangement under one mode of lighting the room, may be quite out of place when the position and distribution of the lights are altered. While, therefore, it is impossible to describe accurately what is a table-plant, it is not difficult to mention several qualities in a plant which would prevent its use for table-decoration. Perhaps it may be more convenient if my remarks are given under the headings of size, height,

Height.—This must be judged from a sitting position and not by anyone standing; and the suitability of a certain plant will often depend upon whether its pot can or cannot be put through the table. Speaking generally, plants fit for the table may be divided into three classes, those which you can see over, those which you can see through, and those which you can see under. Plants which can be looked over must not be more than 15 inches high, and with these dwarf plants (which are placed nearest to the diners) the advantage is immense if you have the power of sinking the pots through the table, since you not only get rid of the ugly pots and of the pot-covers (which are often still more ugly), but you are enabled to employ taller and more graceful plants, and yet not exceed the limit of 15 inches. Plants which can be looked under must have slender stems and foliage that does not fall within 20 inches of the cloth. Plants which can be seen through are those which possess both tall foliage and dwarf foliage, but have no leaves which interrupt the sight between the distances of 15 inches and 20 inches above the table.

Form.—Of dwarf plants, which are below the line of sight, the

Demonorops accidens.

Areodoxa regia.

Demonorops palembanensis.

form, pots, and lighting—an arrangement to which reference can be more readily made than if any other plan were adopted.

Size.—This should be in proportion to the size of the room, since large plants in a small room are out of character, while a number of small plants in a large room, rarely, if ever, produce the good effect which results from the judicious selection and arrangement of a few specimens of suitable dimensions. I mention this, because first impressions have great weight with many people, and it is a point of no small importance with them, that, upon entering a dining-room, there should be nothing out of proportion to disconcert their critical taste. The size of the plants should also be in proportion to the size of the table, and to the size of the other plants used on the table. If a plant is used in the centre of a table, it should be larger than any other on that table. If the table is two or three times as long as it is broad, two plants may be used in the central line of the table; and, these should be a pair, and larger than all the rest. If the table be still longer, a third and still taller plant may be placed in a line between these two, as shown in the three engravings herewith. On wide tables, where more than a central and two side rows can be introduced, the smallest plants should be nearest to the edge.

form is not of any consequence; thick, bushy little plants often look well, if not too crowded; but they look much better when arranged alternately with slender plants of the same height. With taller plants, however, bushy forms are inadmissible; they must always be of slender, elegant, and graceful growth. Tall plants, fit for the table, may be either stemless, like the young forms of *Arecas*, and many other kinds of Palms, in which the long leaf-stalks spring from near the surface of the earth; or with a slender stem which only carries foliage at the top, above the line of sight. In the latter case, a spray of some climbing plant should be twisted round the bare stem, and for this purpose, *Lygodiums* and *Myrsiphyllum asparagoides* are the best climbers that I know of. Another suitable form of tall plant may be exemplified by young *Mimosas* and young *Cupanias*, which have the slender stem furnished at intervals with horizontal leaves or branches, which do not interrupt the view across the table.

Lighting.—When dinners take place, as they usually do, after dark, the illumination of the table or the room is a matter which seriously concerns the table-decorator. His arrangements must, in most cases, be subservient to the mode of lighting, because he cannot

alter that mode, the burners being fixtures. But when a table is lighted by candles or table-lamps, he is not so much hampered in the selection of suitable plants, as he may in that case be able to arrange his lights to show off his plants, and to prevent their casting a shade on the table. The usual mode of lighting, by a gas chandelier suspended over the table, is the worst possible mode for the use of tall plants, because the strong light immediately over them must, of necessity, cast a dark shadow on the cloth, unless the foliage is very finely divided. In such cases it is often better to use some flat decoration of flowers and foliage in the middle of the table, or to use a dwarf plant for the centre, than to introduce any large-foliaged tall specimen. For the display of plants on a table without their throwing a shadow on the white cloth, there is no better plan of illuminating the room than that of bracket-lights, high up, and evenly distributed around the walls, by which arrangement the shadow that any one light would cast (if only that one burner were lighted) is overpowered and destroyed by the light coming from several other burners.

Pots.—These I always put through the table whenever I can; and the tables that I am accustomed to amuse myself in decorating are all of them as full of trap-doors as the stage of a theatre, or perhaps I should rather say, as full of holes as the frame-work that supports the top will permit. Where these conveniences are not yet introduced, the flower-pots must be in some way concealed, either by enclosing them in a circular bed of flowers, or by tying Moss round them (as shown in the accompanying engravings), or by dropping them into one of the numberless forms of covering, made of terracotta, china, glass, cardboard, paper, papier-mache, or wood. Of these I least dislike terracotta.

W. T. P.

THE FRUIT GARDEN.

INARCHING VINES.

THIS is an operation which might be oftener practised with advantage than it is; for many varieties, both strong and healthy, but which do not fruit satisfactorily, are frequently discarded, when they might be profitably utilised in this way. In inarching, the first object should be to select a stock suitable to the variety with which it is to be united, a point on which much depends; for some varieties, when inarched, turn out worse than on their own roots, while others gain in every way by the operation, when suitable stocks have been chosen for them. The varieties from which improvement may be looked for from inarching, are what are known as tender and shy growers, and imperfect fruiters. These demerits, I may mention, are, however, seldom or never universal. I never yet knew a Vine which did not succeed well somewhere; but a certain variety may "flourish like a green Bay tree" in one county, without any special attention, and, indeed, under bad management, and in another district, may not be induced to thrive either by fair or foul means. In such cases as the latter, inarching may be resorted to with advantage. Where a new variety, too, is to be introduced into a Vinery, it is not always practicable to remove a Vine to make room for it; and where a suitable stock exists, it may be "worked" on that without any kind of inconvenience. A whole houseful indeed, of Black Hamburgh might be converted into one of Golden Champion; a houseful of Muscats into one of Barbarossa, or a houseful of diseased and barren Vines into one of health and fertility, all in one season, without disturbing a single rootlet. Vines propagated from eyes and inarched one season, will produce a fair crop the following one, and will grow luxuriantly where root-action has been vigorous from the beginning. Seedling Vines may be rapidly tested by means of inarching. Raised from seed and inarched this year, they may be proved the following season. As to the operation itself, it is extremely simple; the young Vine to be inarched, should have been struck from an eye put into a pot in February, and grown on until May or June; it should then be taken to the Vine which is to form the stock; if growth sufficient to reach the part where the union is to take place, when resting on the ground, has not been made, the pot should be set on some temporary elevation to allow of the union being effected about 12 inches from the base of the stock; when this is done, with a sharp knife cut a small slice about 2 inches long from the side of the young Vine, and then do the same with the stock; these incisions may either be on young green wood, or on old hard stems. Place the two cut portions face

to face, so as to fit exactly; then take a strong piece of soft bast and tie them sufficiently firm together to prevent displacement. In ten days or so they will be partly united, when the bast should be slightly loosened in order to admit of expansion. Do not let the young Vine in the pot suffer from want of water, and in six weeks after being tied together, both stock and scion will be firmly united. The bast should be occasionally looked to in order to prevent its pressing too firmly against the wood, but it should not be taken off altogether until a considerable time after a union has taken place, as the slightest twist will sever the new and tender connection. When a union has been effected beyond a doubt, which generally takes two months to accomplish, the stem of the young Vine immediately below the union should be half cut through, and the stock, above the connection should be treated in a similar way; in another ten days both stock and scion may be cut through, when the young top will get the benefit of a full flow of sap from the root. These remarks apply to Vines which have had their crops removed before a union was effected, for where the Grapes are hanging on a Vine, the top, of course, cannot be cut away; under these circumstances, it is best not to do any cutting until the Vines are pruned, when the whole may be neatly dressed. The union should be as near the bottom of the stock as possible, just about the lowermost spurs where the Vine begins to produce shoots.

As regards stocks, Muscat of Alexandria and Black Hamburgh are the best for general use. I do not know a variety of Grape which will not succeed on either the one or the other. But to confine ourselves to these stocks alone, would not, I fear, meet everybody's requirements. Gros Colman inarched on Black Prince becomes much altered in appearance. The bunches of Gros Colman are, naturally roundish, indeed generally as broad as they are long. Those of Black Prince as is well known, are long and tapering, and singularly enough, the bunches of Gros Colman when on this stock become tapering. Gros Colman is a noble late black Grape, which does well on its own roots everywhere, and inarching in this case is unnecessary. If, however, a plant of it from a cold end of a house is inarched on a Vine at the warmest end, the fruit will ripen more perfectly than it otherwise would do. Black Prince or Black Hamburgh make suitable stocks for it, and Burchardt's Prince is a good stock for white Lady Downes. Burchardt's Prince is a late black Grape of little merit, and as it is generally grown in a late house, the white Lady Downes, which is one of our best late white Grapes, equal indeed, in every respect, to the black variety of that sort, can be conveniently and profitably worked on Burchardt's Prince. Mrs. Pince's Black Muscat, a good late black Grape, but on its own roots a shy setter, succeeds perfectly in every way on the Black Alicante, setting when so treated as freely as that useful kind; Barbarossa (Gros Guillaume) on its own roots is not a very prolific Vine, so far as heavy cropping is concerned, but grafted on the Muscat of Alexandria it does superbly. This fine showy variety ranks amongst the best of late-keeping black Grapes, but it needs heat, and to have it in perfection it should be grown in the temperature of a Muscat-house. West's St. Peters is improved on the Black Hamburgh; Madresfield Court is equally liable to crack and decay when inarched on either the Muscat or Black Hamburgh as on its own roots. Inarching does not appear to improve its condition. Judging from its behaviour here, and elsewhere, I am inclined to think that it will never gain honourable posterity, a circumstance certainly to be regretted, as, up to a certain point, it has a very captivating appearance. I saw it in fine condition last season at Mr. Meredith's, grown on the extension system, a whole house being devoted to it. Waltham Cross has done well here on Black Prince. The appearance of Raisin de Calabre, is improved when "worked" on Black Hamburgh, but the flavour of this variety is against its extensive use. Foster's Seedling does better on White Nice, than on its own roots. The Frontignans, both grizzly and white, are conspicuously enlarged both in bunch and berry when inarched on the Muscat of Alexandria, and their flavour is in no way deteriorated by the union. Muscat Hamburgh is an exquisitely flavoured valuable black Grape when perfectly finished, but it is one of those varieties which does well in but few places on its own roots. It should be "worked" on the Black Hamburgh; thus treated

at Drumlanrig, it is invariably all that could possibly be desired, while, on its own roots it is just the reverse. At Eccles, again, only about two miles from Drumlanrig, it grows, sets, swells, colours, and thoroughly matures three and four bunches on its own roots as perfectly as any Black Hamburgh could do, and that too in a very small confined structure, where one would least expect to find perfect Grapes of any kind. Golden Champion in some places does better grafted than on its own roots, but the finest fruit of it I have ever seen was cut from a Vine of it on its own roots. Black Hamburgh and Muscat of Alexandria make suitable stocks for it. Here we have a considerable number of it on its own roots, and this season it has been unusually fine and free from blemish. Notwithstanding what has been said to the contrary, this Grape can, undoubtedly, be cultivated to perfection, when it amply repays any extra pains that may have been bestowed on it to acquire that condition. Duke of Buccleuch needs no inarching to ensure luxuriant growth or fine fruit; so far as the 100 and odd rods of it here on its own roots are concerned, I may say, that the fruit which they have borne has been in every way, simply, perfect. Mr. David Thomson has, however, grown it at Drumlanrig for years on the Muscat of Alexandria, and his productions are quite equal to any I have seen. At Floors Castle, Mr. Knight has it grafted on the Black Muscat (Muscat Hamburgh), a stock on which it makes splendid growth, equalling that of any young Vine about the place, and as strong and firm as a good substantial walking stick. Mr. Johnson, of Glamis Castle, says: "I have had it on the Hamburgh, Rivers's Sweet Water, and Duchess of Buccleuch, and I find that the two last named varieties have produced by far the best grafts, which are strong, short-jointed, and thoroughly matured. The fruit which I have of it this season (two handsome bunches on one shoot) is the production of a graft put on the Rivers's Sweet Water in the month of May last year. These bunches have ripened and coloured equal to those of a Buckland Sweet Water. They have been ripe upwards of two months, and, to all appearance, will keep as long again."

Clovenfords.

J. Muir.

POTS FOR PINES.

JUST a word or two more on this subject and I have done with it. In the first place, let me remove some misapprehensions under which Mr. Muir is labouring. If he had read my last paper attentively, he would have seen that my remark, "wholly unsupported by theory or practice," had no reference whatever to the pot question, but to the relative size of the plants and the fruit. Neither did I intend to "disparage" moderate-sized fruit, as he imagines, when I spoke of them being preferred for market purposes. I am too familiar with the markets in London, Manchester, Liverpool, and elsewhere, not to know that the greatest trade is done in moderate-sized Pines, say from 2½ to 4 pounds each. Though I grow Pines for a private establishment, I dispose of numbers of surplus fruit every year, and while I could dispose of such fruits off-hand for cash, I find that fruit above 4 or 5 pounds are reluctantly accepted, except to sell on commission. The reason is, that if a customer cannot get a moderate-priced Pine to ornament his dessert, he will do without it rather than pay, perhaps, £3 or £4 for a single fruit. Mr. Muir should also bear in mind, as I hinted before, that this discussion has no reference to such things as "spongy wood," "over luxuriance," and such like; nor yet to Vines, though I am prepared to maintain the well-established fact, that the strongest Vine cane, no matter how strong, is the best for all purposes, if well ripened; and if this is not the opinion of Vine-growers of note, I have mistaken the whole tenour of their teaching and practice. It will be new to Pine growers to learn from Mr. Muir that the smooth Cayenne is a weaker grower than the Queen. Let Mr. Thomson note this in his next edition on the "Pine," for in the present edition the smooth-leaved Pine is described as being both taller and broader in habit than the Queen, with "very broad leaves;" and this description every Pine grower believes to be correct. We are told, moreover, by your correspondent, that the smooth-leaved Cayenne yields heavier fruit than the Queen, because it is its nature to do so. Surely he did not imagine that I meant to dispute such a "natural" deduction, because I offered a reasonable explanation for the difference in the two varieties. Mr. Muir surely believes in such a thing as "cause and effect," and if he does, will he tell us why smooth-leaved Cayennes, Rothschilds, and Providences yield the largest fruit? Can he get to any other legitimate conclusion, than that the fruit of these varieties is larger than the Queen, because the plants are larger and more vigorous? and if he

admits this, why should a strong Queen plant not yield a larger fruit than a weak one? When a batch of suckers shows fruit prematurely, are the fruits not always in exact proportion to the size of the suckers? and would they not be larger after the plants had added six months to their age? Taken singly, or in the aggregate, the largest plants will undoubtedly yield the best results—all other things being equal. This is the point at issue, and one which I hope Mr. Muir will observe and adhere to. If he can furnish any other logical solution, based upon physiological principles, or consistent with general experience, I hope he will do so. I cut a number of Queen's lately, and the largest of them was from the largest plant, and weighed 5 pounds 9 ounces, beautifully formed and finished. The stock or stem of this plant and others would have filled a 9-inch pot without there being room for any soil. I use 10, 12, and 14-inch pots, according to the size of the plants, and never fail to get all crammed with roots, like a Strawberry pot, nor fail to get almost every plant to show fruit at the time desired, year after year. The fact is, there need be no difficulty in getting Pines to show fruit when wanted, if the plants are well ripened. I saw, at Mr. Miles's place (Wycombe Abbey), last year, a division containing about thirty plants (Queens), not one of which had missed; nor would there be, I guessed, one fruit under 5 pounds, and many would be about 6 pounds weight, which Mr. Miles has frequently exhibited in London and elsewhere. The plants which bore these fruits were in 12 and 14-inch pots, and were uncommonly sturdy and strong, with leaves twice the usual thickness. I have to thank Mr. Muir for the measures of the pots which he furnishes; but, though he says he has always found the pots to correspond with the figures, both in England and in Scotland, the Scotch big 10-inch pot is no myth. I believe it is made in Glasgow, and I was under the impression it was the pot referred to by Mr. Muir; as, unless my memory misleads me, in a report of Clovenfords, which appeared in one or other of the gardening periodicals awhile ago, this pot is described as being in use for Pines there. Unfortunately, I cannot lay my hand on the number containing the report, and it is just possible I may have been mistaken. I freely admit, however, that, if Mr. Muir gets 4 pound fruit generally from 9-inch pots, he accomplishes a creditable feat; hitherto I have not seen this done in anything like a regular way. From big suckers—such as Pines in 9-inch pots will not yield when carrying large fruit at the same time—I have got large fruit, and seen the same obtained by others in small pots; but the suckers were raised under different conditions, and, we might say, just put into a small pot to fruit. Mr. Muir questions my statement respecting the Providence producing the largest fruit, and says the Lambton Castle Pine is the largest. I have not seen that variety; but I understand it is a very vigorous grower; yet I have not heard of any fruit of it weighing 15 lb.—a weight to which the Providence once reached at Gunnersbury. I have seen Pines planted out at Frogmore that would come near this weight. The plants were big for Providence, owing to being planted out, and the fruit was consequently large too. By-the-by, how does your correspondent get over the difficulty that planted-out Pines always produce the largest fruit—a fact too well established to be at all disputed?

A PINE GROWER.

BUYING POT VINES.

It may be stated with safety, I think, that no kind of fruit tree is propagated every year for sale so extensively as the Grape Vine. Thousands are annually grown and sold for planting and fruiting in pots. What becomes of them all, and what success buyers experience with their stock generally, it is impossible to tell; but I have no doubt that, if the truth was known, it would be a history of failure in many instances. Inexperienced cultivators buy largely, some for planting, and others with the object of fruiting their plants the following season, in the sanguine expectation that they will have a crop of nice Grapes at once; but disappointment is often the result. I speak from what I have seen. Clergymen, with perhaps a small glass house or two, retired men of business, and such like, go to a nursery for their Vines, in the simple faith that healthy or fruitful plants are only a question of price. Gross wood and foliage to them indicate perfection, and no doubt twelve pot vines, capable of bearing one hundred or more pounds of grapes, for the moderate sum of £6 or thereabouts, appears an excellent speculation; and so it would be, and such a result is nothing more than might be expected from really good canes; but the nurserymen do not, as a rule, produce such Vines, though I freely admit there are honourable exceptions. It is a significant fact that experienced gardeners never buy pot Vines for fruiting, if they can help it, but grow their own stock; and when they do buy, they find it exceedingly difficult to get what they want. For instance, plants fit to start in November for a crop in March and April can hardly ever be bought from the

trade; such plants are often advertised; but, instead of Vines that have been brown and ripe in June and July, and at rest and quite fit to prune in August or the beginning of September, you often find them to be green and succulent in the leaves even at the beginning of October, and quite unfit to be started till January at the soonest. I have occasionally sought to buy for myself or others early pot Vines, but never could find anything better than I describe. Growing pot Vines in bottom-heat, a practice fatal to all future success, has, however, been discontinued in many respectable nurseries, though vast numbers of this sort are still grown. Customers should never buy such plants, for they are good for nothing. Turned out of a hot-bed, and sent very likely from the grower to the salesman—who place them out-of-doors to turn the leaves yellow and give them a matured appearance—and thence to the buyer, the roots get killed, or, at the least, so greatly injured by the transition from heat to cold, as to render them worthless afterwards, either for planting or fruiting purposes. I had a score of Vines of this type sent to me once for planting; the canes looked vigorous, but, on shifting the plants out of the pots, I found every root black and dead. They were bought as plants “grown without bottom-heat;” but, finding this was not true, I refused to pay for them, and the claim was not pushed. A little experience will enable anyone to know a well-ripened Vine at once, and even to tell if bottom-heat has been applied to it. Vines intended for forcing early should be bought in in August or September, by which time the foliage should be assuming an autumn tint, and the canes be brown and hard. Varieties differ in the colour of their bark, some, such as the Hamburgh and Royal Muscadine, being darker than others; but all should be of a nutty-brown colour, and clean and shiny. Avoid canes of a pale whitish look, for they are always ill grown. See that the buds at the axils of the leaves are fully developed, brown, firm, and as plump as small Filberts. The thicker the canes the better, if they are well ripened, which you can tell by cutting a section of the wood with the knife. If it cuts hard, and the pith is not thicker than a pin, you may be satisfied. Vines said to be as hard as Oak are mythical. Look narrowly at the bark, and if you observe dusky circular patches here and there like a faded soot-black, mildew has been there for certain, and will return again if the canes are not thoroughly washed and sulphured before starting, and the usual precautions taken. In healthy grown Vines the roots correspond with the branches. Turn the plant carefully out of the pot—it will do no harm to a properly rooted Vine—and if the roots are long, generally thick and fleshy, and much congregated at the bottom of the pot, they must be suspected of “bottom-heat” treatment; otherwise, if the roots are small, wiry, and pretty equally distributed round the sides of the ball, it is a good sign. Being satisfied with your bargain, have the plants sent home at once, and set out in some sheltered situation till they are pruned, taking care to protect the roots from exposure to the weather by tucking some short dry litter amongst the pots, but not by any means sufficient to ferment. But what about the “Phylloxera?” it will be asked. It must be admitted that the presence of this enemy in the country should make anyone hesitate to buy Vines at all when there are permanent Vineries on the place. But many cannot do otherwise; hence, they must be careful where and how they buy. Nurserymen have more interest in keeping their stock clean than anyone else; and I believe many of them are now careful either to save eyes for propagating from their own stock, or to get them from some private garden, which is known to be safe, regularly; so that all that customers can do, and should do, is to inquire into these matters, and obtain references from the firm with which they deal—and, above all, to scrutinise the Vines well before they buy them, both roots and leaves, with a lens, for it is well known that the insect may be there, though no indications of its presence may be visible at the time. J. S. W.

“SWEET” APPLES.

It is a common opinion that sweet Apples only are properly adapted to the feeding of pigs and cattle. There is no doubt that rich and sweet fruits are excellent for this purpose, but our observations do not tend to prove their pre-eminence over rich Apples that are sub-acid. We have fed cows, horses, and swine on both sorts. Like all succulent food, they tend to promote the health of all these animals, if regularly given in moderate quantities. Nearly the whole of the fattening of large swine has been well accomplished with the droppings of an orchard, nineteen-twentieths of which were sub-acid fruits. We should, however, prefer sweet Apples in planting new orchards exclusively for domestic animals. They are not enough planted for culinary purposes, as they are always excellent for baking, and they may be employed economically in certain puddings for the table. In order to call attention more particularly to planting sweet varieties, we give the following brief descriptive

list of most of the well known sorts, beginning with the earliest. The Sweet Bough, or Large Yellow Bough, is undoubtedly the most valuable of the earliest varieties. The tree, although not a strong grower, forms a round even head, and bears regularly and moderately; the fruit is large, handsome, and one of the most agreeable of all sweet Apples for the table, ripening immediately after our Wheat harvests. The refuse or inferior specimens might be profitably given to domestic animals. Immediately following the Bough are Golden Sweet and High-top Sweet, both vigorous growers and good bearers, the latter known in the west by the name Sweet June. Summer Sweet Paradise is a large good Apple, ripening nearly with the two last named; the tree is a rather straggling grower, and not so certain in its crops. Autumn Sweet Bough, or Philadelphia Sweet, is a medium-sized pale-yellow Apple, ribbed and farrowed, with good flavour, the tree quite productive. In autumn, we have Jersey Sweet during September, a good Apple, of medium size, the tree very productive, but a moderate grower, and not always hardy and healthy. Autumnal Swaar, a fine vigorous grower, good bearer, the fruit good size, rich yellow, oblate, excellent in quality, ripening about mid-autumn. Closely following this is Munson Sweet, also a good grower, and handsome fair fruit of excellent quality. Haskell Sweet is a large autumn variety, of excellent flavour; but, unlike the two last, somewhat liable to scabs or spots. The tree is a moderate grower, but great bearer. Lyman's Pumpkin Sweet is remarkable for the handsome growth of the tree and its great productiveness; the fruit quite large, always fair, but not so agreeable in flavour as most of this class; it is, however, a valuable sort. Among the early winter Apples are Bailey's Sweet, Ramsdell's Sweet, and Honey Greening. Bailey's is a large handsome red Apple, tender, sweet, and agreeable, the tree a strong grower and good bearer, and altogether a valuable sort. Ramsdell's is equally vigorous as a grower, quite productive, large, but of moderate quality. Honey Greening (distinct from Green Sweet, to which the name is sometimes applied) is an oblate, yellow fruit, very sweet, and of good quality; the tree of spreading growth.

There are several later winter sorts, prominent among which for wide popularity is the Tallman Sweet, on account of its excellent quality, fair appearance, and productiveness. The trees when young grow vigorously, but they never attain large size. As a proof of the wide approval of this Apple, it is starred in twenty different States of the Union in the catalogue of the American Pomological Society, with double stars in four. Danvers Sweet, ripening about the same time, is a freer and larger grower, and usually more productive, but the fruit is not equal to the last mentioned in quality. Hartford Sweeting, a large, dull red Apple, is borne on a vigorous tree, but is hardly of first quality; Ladies' Sweet, on the other hand, is an excellent Apple, of medium size, but the tree is a feeble grower. Phillips' Sweeting, of Ohio, somewhat resembles Ladies' Sweeting, but is hardly so good in flavour; it is more showy, and grows on a more vigorous tree, and altogether is a valuable sort. The old Sweet Pearmain, a well-known roundish conical dark red Apple, is much valued at the West, as well as the Sweet Romanite, more oblate in form, and lightly striped with red, keeping through winter. The tree of the Sweet Vendevre is crooked and straggling, but it bears heavy crops of a rich, juicy, and aromatic fruit. The Wing Sweeting, when fair, is a handsome, brilliant red Apple of fine flavour, but is not always reliable. Green Sweet is a moderately good sort, growing on a strong, healthy tree. Broadwell and Winter Sweet Paradise are valuable winter sorts in the west. We could add many more names to the preceding list, some of the sorts of considerable merit.—*Cultivator.*

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Weights of Pine-apples Grown at Frogmore.—I am told that Providences have been grown at Frogmore weighing 15 lbs. each. Is that a fact?—*INQUIRY.* [No; the heaviest Providences grown at Frogmore were two fruit ripened there about twenty-five years ago; one of which weighed 11 lbs. 12 ozs., and the other 11 lbs. 4 ozs. The former was from a sucker, the latter from a crown of a fruit, stated to have weighed 15 lbs., grown at Gimmersbury. The age of both the plants when the fruit was cut was twenty months. It may be added that the heaviest Smooth-leaved Cayenne ever grown at Frogmore weighed 11 lbs. 2 ozs. That was in 1855, and was probably the first fruit of that sort grown in England.]

Standard Fig Trees in Kent.—I have sent you a sample of Figs to prove that standard Figs can be grown in Kent as well as in Sussex. I quite agree with your remark (see p. 229) that in many places in England they might be grown in great perfection, particularly in the southern districts. I have here two trees of the Brunswick in the kitchen garden, which I raised and planted out about fifteen years ago; they have borne some nice crops. As they make short jointed wood I never prune them. One has a 5 feet stem, the other, 4½; an 18 inch circumference they measure, respectively, 22 inches at the base, and 18 inches. Where they branch out into heads, the latter measure 16 feet through, and I droop to the ground. I grow the same variety on walls from which I have gathered fruit weighing 3½ lbs. each. Some varieties are more hardy than the Brunswick, but not so good in flavour.—*W. DIXES, Gardener to Wm. Moore, Esq., Winton House, Maidstone.* The Figs sent were as large and fine as any we ever saw grown, either against a wall or under glass.]

THE INDOOR GARDEN.

THE EDIBLE PASSION-FLOWER.

(PASSIFLORA EDULIS.)

Flw greenhouse or conservatory climbers are more beautiful than this, and yet it is rarely one meets with it in modern collections. Planted out in a border of rich moist earth, it grows rapidly, often making shoots 10 and 12 feet long in a single season; and, when in vigorous health, gracefully draping pillars, arches, or rafters, with a profusion of glossy foliage. The flowers, although ornamental, are not so showy as those of many of the other species; but, under good culture, they are succeeded by bright purple fruits, each the size of a hen's egg, and which are favourites with many on account of their fine sub-acid flavour. Although, however, this is undoubtedly the best of all the edible Passion-flowers, *P. macrocarpa* and *P. quadrangularis* are by no means useless additions to the dessert, and those who have not acquired a taste for them in a fresh state rarely fail to relish them

Fruit of *Passiflora edulis*.

when preserved. Even, however, in the absence of fruit, *P. edulis* well deserves cultivation, as it is the most beautiful of all the *Passifloras* in habit, *P. (racemosa) princeps* not even excepted. I have often used the deep glossy leaves of *P. edulis* for garnishing fruit; and, for toning down bright colours, they are especially valuable, on account of the dense metallic depth of green which they possess. Like most of its congeners it is readily propagated either by means of cuttings, layers, or seeds, and those who require a climber of a deep tint, for the ornamentation of a conservatory or corridor, cannot do better than avail themselves of it. Our illustration represents a fruit of the natural size, but gives no idea of the grace and beauty of the plant. B.

ORCHIDS AT DOWN HOUSE, BLANDFORD.

THE remarks in the pages of THE GARDEN some weeks ago in reference to cut blooms of *Disa grandiflora* grown at Down House, Blandford, the residence of Sir William Marriott, necessarily give but an inadequate idea of the grandeur of this plant as a whole; the individual

spikes are fine, but a plant with thirty-two open flowers, on spikes 4 feet high, in the highest state of cultivation, is a sight indeed. At the end of July, I had the pleasure of seeing four such plants, or, rather, pans of plants, in the conservatory at Down House, besides sundry plants, on each of which there were several flowers, and anything more striking in the shape of an Orchid I never before witnessed. These *Disas* are grown in the coolest end of a cool *Odontoglossum*-house with a north aspect and close to the glass. They receive abundance of water in winter and spring, and a moist atmosphere is maintained for them; but a constant supply of fresh air is kept up about the plants, in order to mature their growth as it progresses. Numbers of other plants, equally bear witness to Mr. Hill's skill as a cultivator. For instance, I noticed plants of *Cattleya Aclandiae*, a difficult plant to grow, and of the rare *Oncidium Rogerii*; also very fine plants of *Cymbidium eburneum* and *Vanda cerulea*, in the *Cattleya*-house. Many fine *Dendrobiums* also occupy the East India house, such as *D. Falconeri*, *D. Wardianum*, and a splendid plant of *D. thyrsiflorum*; *Cattleya superba* also does best in this house. There were, moreover, fine plants of *Aerides Fieldingii*, and *A. quinquevulnerum* and *affine*. Here, too, were fine pans of various *Anectochili*, which visitors to the Bath and West of England shows at Bristol and Dorchester will remember. They consisted of *Lowii*, *Dayii*, *Dawsonii*, *Zanthophylla*, and others. On a former visit, I noticed many of the *Dendrobiums* in baskets suspended in a lean-to house, close to the glass in the full blaze of the sun, in order to ripen them for flowering. I also recollect seeing fine masses of *Pleione lagenaria*, *maculata*, and others; quantities of *Calanthe Veitchii*, *vestita*, *rubro-occulata*, and *lutea-occulata*, *Phalenopsis*, and many others. The *Odontoglossum*-house contains a fine collection of plants in wonderful health, and among them quantities of *Masdevallias*, consisting of *Veitchii*, a fine plant of *Lindeni*, *igneae*, and *Harryana*. Among the rare *Odontoglossums* were *miniatum*, *navium majus*, and a magnificent plant of *O. zebrinum*, with a spike 12 feet long. These are only a few of the many fine plants to be found in this rich collection. Among plants of another kind I noticed an immense example of *Lapageria rosea*, bearing hundreds of blooms spreading over one side of the conservatory, and throwing up great *Asparagus*-like shoots from among rough clods of soil under the stage. There were also quantities of finely-grown *Tuberoses*, both double and single, Italian and American. Allow me to add also that, among fruit, Peaches were in the finest health, and bearing crops of brilliantly coloured fruit; also Nectarines, on trees not twelve months planted under glass. Of Pines there were quantities, and most promising plants of Strawberries in pots.

Canford.

WILLIAM DICK.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Greenhouse Plants for Winter Blooming: W. R. The best are *Lapageria rosea*, *L. alba*, *Bourvandia leiantha compacta* and *jasminoides*, *Acacia Drummondii*, *platyptera*, and *oleifolia elegans*; *Statice profusa*, *Epacris* in variety, *Richardia aethiopica*, *Monochaetum sericeum*, *multidorum*, *Camellias* of sorts, *Cinerarias* of sorts, *Azaleas* of sorts, *Cyclamens* of sorts, Chinese *Primroses*, *Daphne indicæ rubra*, *Hyacinths*, *Tulips*, and *Narcissus* of sorts; *Andromeda floribunda* (hardy), *Tree Carnations*, *Erica hyemalis*, *gracilis*, *grandiflora*, *colorans*, *cafra*, and many others; several good sorts of *Rhododendrons*, *Lilacs*, double white Almond and Tea Roses (all forced), *Jasminum graniflorum*, *Cassia corymbosa*, *Chorozema Lawrenceana*, *Coronilla glauca*, several sorts of *Correa*, *Cytisus Alceana*, *Leschenaultia intermedia* and *Baxteri major*, and *Leucopogon Cunninghamii*.—JOHN FRASER.

Greenly on Ferns: F. M. Fumigate them with good tobacco paper when the fronds have acquired firmness of texture; if the plants are making young growth, syringe with tobacco-water instead.

Azaleas from Cuttings: T. E. When the young wood of the current season's growth is nearly ripe, it is in a proper state to make cuttings of. Insert the cuttings, not too closely, in 6-inch pots, in silver sand; cover with a bell-glass, shade from the sun. Strike in a gentle bottom-heat. As soon as struck, pot off the cuttings into 3-inch pots in peat and sand, and grow on liberally for two years in a warm or intermediate house.

Gloxinias from Leaves: W. F. Insert the leaf half-way into the soil, any time after the leaves are fully formed; or cut the ribs into short lengths, with a portion of the leaf attached, and insert these edgewise like ordinary cuttings in silver sand. Place them in a hot-bed or warm propagating pit, shade and water moderately. Or cut through the mid-rib at intervals, fix the lower end of each portion with a peg, put some silver sand about the cut, and keep shaded in a close frame with a brisk heat. They should root from every cut.

Bertolonia Van Houttei and Begonias at Ghent.—On visiting Mr. Van Houtte's establishment at Ghent, I was much pleased with a magnificent variegated plant, and, on enquiry, found it to be a seedling *Bertolonia* raised in that establishment, and called Van Houttei. Its leaves are dark green, beautifully reticulated with Solferino pink, a colour quite new amongst variegated plants. I also saw here some wonderfully fine plants of seedling *Begonias*, which had been treated as follows:—The seed was sown in pans early in the year, and in May the young seedlings were planted out in a cold frame, where they were slightly protected till they took fresh root; the lights were then taken off, and in this frame they made their growth and flowered in September. The individual flowers vary from 2 to 3 inches in diameter, and are of all shades of colour. These plants, when in blossom, are taken up and potted, and some thousands of them in one of the greenhouses certainly had a striking appearance. So many plants in flower at this season are not often met with. I may add that the soil in which they were planted had been well manured.—F. H.

THE FLOWER GARDEN.

WATER LILIES.

INCONSTANT April mornings drop showers or sunbeams over the glistening lake, while far beneath its surface a murky mass disengages itself from the muddy bottom, and rises slowly through the water. The tasselled Alder branches droop above it, and newly-opened Hepaticas and Epigeas on a neighbouring bank peer down modestly to look for it. Wishing to see these treasures of the lake in their morning hour, we encamped on a little island, which one tall tree almost covers with its branches, while a dense undergrowth of young Chestnuts and Birches fills all the intervening spaces, touching the water all around the circular shelving shore. We kindled a gypsy fire of twigs, less for warmth than for society. The first gleam made the dark lonely islet into a cheering home, turned the protecting tree to a starlit roof, and the Chestnut sprays to illuminated walls. Lying beneath their shelter, every fresh flickering of the fire kindled the leaves into brightness and banished into dark interstices the lake and sky; then the fire died into embers, the leaves faded into solid darkness in their turn, and water and heavens showed light and close and near, until fresh twigs caught fire and the blaze came up again. Rising to look forth at intervals during the night—for it is the worst feature of a night out-doors, that sleeping seems such a waste of time—we watched the lilly and wooded shores of the lake sink into gloom and glimmer into dawn again, amid the low plash of waters and the noises of the night. Precisely at half-past three, a sparrow above our heads gave one liquid trill, so inexpressibly sudden and delicious that it seemed to set to music every atom of freshness and fragrance that Nature held; then the spell was broken, and the whole shore and lake were vocal with song. Joining in this jubilee of morning, we were early in motion; bathing and breakfast, though they seemed indisputably in accordance with the instincts of the Universe, yet did not detain us long, and we were promptly on our way to Lily pond. Will the reader join us? Almost every town has its Lily pond. Ours is accessible from the larger lake only by taking the skiff over a narrow embankment, which protects our fairyland by its presence. Once beyond it, we are in a realm of dark Lethean water utterly unlike the sunny depths of the main lake. Hither the Water Lilies have retreated, to a domain of their own. A decline in business is clear revenue to Water Lilies, and the waters are higher than usual because factories are idle. But we may notice, in observing the shores, that peculiar charm of water, that, whether its quantity be greater or less, its grace is the same; it makes its own boundary in lake or river, and where its edge is, there seems the natural and permanent margin. And the same natural fitness, without reference to mere quantity, extends to its children. Before us lie islands and continents of Lilies, acres of charms, whole, vast, unbroken surfaces of stainless whiteness. And yet, as we approach them, every insulated cup that floats in lonely dignity, apart from the multitude, appears as perfect in itself, couched in white expanded perfection, its reflection taking a faint glory of pink that is scarcely perceptible in the flower. As we glide gently among them, the air grows fragrant, and a stray breeze flaps the leaves, as if to welcome us. Each floating flower becomes suddenly a ship at anchor, or rather seems beating up against the summer wind, in a regatta of blossoms. Early as it is, the greater part of the flowers are already expanded. Indeed, that experience of Thoreau's, of watching them open in the first sunbeams, rank by rank, is not easily obtained, unless perhaps in a narrow stream, where the beautiful slumberers are more regularly marshalled. In our lake, at least, they open irregularly, though rapidly. But, this morning, many linger as buds, while others peer up, in half-expanded beauty, beneath the lifted leaves, frolicsome as Pucks or baby-nymphs. As you raise the leaf, in such cases, it is impossible not to imagine that a pair of tiny hands have upheld it, or else that the pretty head will dip down again, and disappear. Others, again, have expanded all but the inmost pair of white petals, and these spring apart at the first touch of the finger on the stem. Some spread vast vases of fragrance six or seven inches in diameter, while others are small and delicate, with petals like fine lace-work. Smaller still, we sometimes pass a flotilla of infant leaves, an inch in diameter. All these grow from the deep, dark water—and the blacker it is, the fairer their whiteness shows. But your eye follows the stem often vainly into those sombre depths, and vainly seeks to behold Sabrina fair, sitting with her twisted braids of Lilies, beneath the glassy, cool, but not translucent wave. Do not start, when, in such an effort, only your own dreamy face looks back upon you, beyond the gunwale of the reflected boat, and you find that you float double, self and shadow. Let us rest our paddles, and look round us, while the idle motion sways our light skiff onwards, now half-embayed among the Lily pads, now lazily

gliding over intervening gulfs. There is a great deal going on in these waters and their fringing woods and meadows. All the summer long, the pond is bordered with successive walls of flowers. In early spring emerge the yellow catkins of the Swamp Willow, first; then the long tassels of the graceful Alders expand and droop, till they weep their yellow dust upon the water; then come the Birch blossoms, more tardily; then the downy leaves and white clusters of the Medlar or Shadbush (*Amelanchier canadensis* of Gray); these dropping, the roseate chafes of the Mountain Laurel open; as they fade into melancholy brown, the sweet Azalea uncloses; and before its last honeyed blossom has trailed down, dying, from the stem, the more fragrant *Clethra* starts out above, the Buttonbush thrusts forth its merry face amid wild Roses, and the Clematis waves its sprays of beauty. Mingled with these grow, lower, the Spiræas, white and pink, yellow Touch-me-not, fresh white Arrowhead, bright blue Vervain and Skullcap, dull Snakehead, gay Monkey-flower, coarse Eupatoriums, Milk-weeds, Golden-rods, Asters, Thistles, and a host beside. Beneath, the brilliant scarlet Cardinal-flower begins to palisade the moist shores; and after its superb reflection has passed away from the waters, the grotesque Witch Hazel flares out its narrow yellow petals amidst the October leaves, and so ends the floral year. There is not a week during all these months, when one cannot stand in the boat and wreath garlands of blossoms from the shores. These all crowd around the brink, and watch, day and night, the opening and closing of the Water Lilies. Meanwhile, upon the waters, our queen keeps her chosen court, nor can one of these mere land-loving blossoms touch the hem of her garment. In truth, she bears no sister near her throne. There is but this one species among us, *Nymphaea odorata*. The beautiful little rose-coloured *Nymphaea sanguinea*, which once adorned the Botanic Garden at Cambridge, was merely an occasional variety of costume. She has, indeed, an English half-sister, *Nymphaea alba*, less beautiful, less fragrant, but keeping more fashionable hours—not opening (according to Linnaeus) till seven, nor closing till four. Her humble cousin, the yellow Naphar, keeps commonly aloof, as becomes a poor relation, though created from the selfsame mud—a fact which Hawthorne has beautifully moralised. Undisturbed, however, the Water Lily keeps her fragrant court, with few attendants. The tall Pickerel-weed (*Pontederia*) is her gentleman-usher, gorgeous in blue and gold through July, somewhat rusty in August. The Water-shield (*Hydroptilis*) is chief maid-of-honour; she is a highborn lady, not without royal blood indeed, but with rather a bend sinister; not precisely beautiful, but very fastidious; encased over her whole person with a gelatinous covering, literally a starched duenna. Sometimes she is suspected of conspiring to drive her mistress from the throne; for we have observed certain slow watercourses where the leaves of the Water Lily have been almost wholly replaced by the similar, but smaller, leaves of the Water-shield. More rarely seen is the slender *Utricularia*, a dainty maiden, whose light feet scarce touch the water—with the still more delicate floating white Water Ranunculus, and the shy Villarsia, whose submerged flowers merely peep one day above the surface and then close again for ever. Then there are many humbler attendants, Potamogetons or Pond-weeds. And here float little emissaries from the dominions of land; for the fallen florets of the *Viburnum* drift among the Lily pads, with mast-like stamens erect, sprinkling the water with a strange beauty, and cheating us with the promise of a new aquatic flower. These are the still life of this sequestered nook; but it is in fact a crowded thoroughfare. No tropical jungle more swarms with busy existence than these midsummer waters and their bushy banks.

Gathering Water Lilies.

Every flower bears a fragrant California in its bosom, and you hesitate to leave one behind. But, after the first half-hour of eager grasping, one becomes fastidious, rather scorns those on which the wasps and flies have alighted, and seeks only the stainless. But handle them tenderly, as if you loved them. Do not grasp at the open flower as if it were a Pæony or a Hollyhock, for then it will come off, stalkless, in your hand, and you will cast it blighted upon the water; but coil your thumb and second finger affectionately around it, press the extended forefinger firmly to the stem below, and with one steady pull you will secure a long and delicate stalk. Consider the Lilies. All over our rural watercourses, at midsummer, float these cups of snow. They are Nature's symbols of coolness. They suggest to us the white garments of their Oriental worshippers. They come with the white Roses, and prepare the way for the white Lilies of the garden. The Water Lily comes of an ancient and sacred family. It has assisted at the most momentous religious ceremonies, from the beginning of recorded time. The Egyptian Lotus was a sacred plant; it was dedicated to Harpocrates and to Nofr Atmoo—Nofr meaning *good*, whence the name of our yellow Lily, Naphar. But the true Egyptian

flower was *Nymphaea Lotus*, though *Nymphaea carnea*, Moore's "blue Water Lilies," can be traced on the sculptures also. It was cultivated in tanks in the gardens; it was the chief material for festal wreaths; a single bud hung over the forehead of many a queenly dame; and the sculptures represent the weary flowers as dropping from the heated hands of *belles*, in the later hours of the feast. Rock softly on the waves, fair Lilies! your Eastern kindred have rocked on the stormier bosom of Cleopatra. The Egyptian Lotus was, moreover, the emblem of the sacred Nile, as the Hindoo species of the sacred Ganges; and both the one and the other was held the symbol of the creation of the world from the waters. The sacred bull, Apis, was wreathed with its garlands; there were niches for water, to place it among tombs; it was carved in the capitals of columns; it was represented on plates and vases; the sculptures show it in many sacred uses, even as a burnt offering; Isis holds it; and the god Nilus still binds a wreath of Water Lilies around the throne of Memnon. From Egypt the Lotus was carried to Assyria, and Layard found it among Fir cones and Honeysuckles on the later sculptures of Nineveh. The Greeks dedicated it to the nymphs, whence the name *Nymphaea*. Nor did the Romans disregard it, though the Lotus to which Ovid's nymph Lotis was changed *seruato nomine*, was a tree, and not a flower. Still different a thing was the enchanted stem of the Lotus-eaters of Herodotus, which prosaic botanists have reduced to the *Zizyphus Lotus* found by Mungo Park, translating also the yellow Lotus dust into a mere "farina, tasting like sweet ginger-bread." But, in the Lotus of Hindostan, we find our flower again, and the Oriental sacred books are cool with Water Lilies. The orb of the earth is Lotus-shaped, and is upborne by the tusks of Vesava, as if he had been sporting in a lake where the leaves and blossoms float. Having got thus far into Orientalism, we can hardly expect to get out again without some slight entanglement in philology. Lily pads. Whence *pads*? No other leaf is identified with that singular monosyllable. Has our floating Lotus leaf any connection with padding, or with a footpad? With the ambling pad of an abbot, or a paddle, or a paddock, or a padlock? with many-domed Padua proud, or with St. Patrick? Is the name derived from the Anglo-Saxon *paed* or *petthian*? All the etymologists are silent on the subject; Tooke and Richardson ignore the problem; and of the innumerable pamphlets in the Worcester and Webster controversy, leading the tables of school-committeemen, not one ventures to grapple with the Lily pad. The Sanscrit name for the Lotus is simply *Padma*. The learned Brahmins call the Egyptian deities Padma Devi, or Lotus gods; the second of the eighteen Hindoo Puranas is styled the Padma Purana, because it treats of the "epoch when the world was a golden Lotus;" and the sacred incantation which goes murmuring through Tibet is "Om mani padme houn." It would be singular, if upon these delicate floating leaves a fragment of our earliest vernacular has been borne down to us, so that here the schoolboy is more learned than the *savans*. This lets us down easily to the more familiar uses of this plant divine. By the Nile, in early days, the Water Lily was good not merely for devotion, but for diet. "From the seeds of the Lotus," said Pliny, "the Egyptians make bread." The Hindoos still eat the seeds roasted in sand; also the stalks and roots. In South America, from the seed of the Victoria (*Nymphaea Victoria*, now *Victoria regia*) a farina is made, preferred to that of the finest Wheat—Bonpland even suggesting to our reluctant imagination Victorias. But the European species are used, as far as we know, only in dyeing. Our own Water Lily has some strange peculiarities of structure. So loose is the internal distribution of its tissues, that it was for some time held doubtful to which of the two great vegetable divisions, exogenous or endogenous, it belonged. Its petals, moreover, furnish the best examples of the gradual transition of petals into stamens—illustrating that wonderful law of identity which is the great discovery of modern science. Every child knows this peculiarity of the Water Lily, but the extent of it seems to vary with season and locality, and sometimes one finds a succession of flowers almost entirely free from this confusion of organs. Our readers may not care to know that the order of *Nymphaeaceae* "differs from *Ranunculaceae* in the consolidation of its carpels, from *Papaveraceae* in the placentation not being parietal, and from *Nelumbiaceae* in the want of a large truncated disc containing monospermous achenia;" but they may like to know that the Water Lily has relations on land, in all gradations of society, from Poppy to Magnolia, and yet does not conform its habits precisely to those of any of them. Its great black roots, sometimes as large as a man's arm, form a network at the bottom of the water. Its stem floats, an airy four-celled tube, adapting itself to the depth, though never stiff in shallows, like the stalk of the Yellow Lily; and it contracts and curves when seed-time approaches, though not so ingeniously as the spiral threads of the European *Vallisneria*, which uncoil to let the flowers rise to the surface, and then cautiously retract, that the seeds may ripen on the very bottom of the lake. The leaves show beneath the magnificently beautiful adap-

tations of structure. They are not, like those of land-plants, constructed with deep veins to receive the rain and conduct it to the stem, but are smooth and glossy, and of even surface. The leaves of land-vegetation have also thousands of little breathing-pores, principally on the under side: the Apple leaf, for instance, has twenty-four thousand to a square inch. But here they are fewer; they are wholly on the upper side, and, whereas in other cases they open or shut according to the moisture of the atmosphere, here the greedy leaves, secure of moisture, scarcely deign to close them. Nevertheless, even these give some recognition of hygrometric necessities, and, though living on the water, and not merely christened with dewdrops like other leaves, but baptised by immersion all the time, they are yet known to suffer in drought and apparently to take pleasure in heavy falls of rain.

The Royal Water Lily.

We have spoken of the various kindred of the Water Lily; but we must not leave our fragrant subject without due mention of its most magnificent, most lovely, relative, at first claimed even as its twin sister, and classed as a *Nymphaea*. We once lived near neighbour to a Victoria regia. Nothing, in the world of vegetable existence, has such a human interest. The charm is not in the mere size of the plant, which disappoints everybody, as Niagara does, when tried by that sole standard. The leaves of the Victoria, indeed, attain a diameter of 6 feet; the largest flowers, of 23 inches—less than four times the size of the largest of our Water Lilies. But it is not the mere looks of the Victoria, it is its life which fascinates. It is not a thing merely of dimensions, nor merely of beauty, but a creature of vitality and motion. Those vast leaves expand and change almost visibly. They have been known to grow half-an-inch an hour, 8 inches a day. Rising one day from the water, a mere clenched mass of yellow prickles, a leaf is transformed the next day to a crimson salver, gorgeously tinted on its upturned rim. Then it spreads into a raft of green, armed with long thorns, and supported by a framework of ribs and cross-pieces, an inch thick, and so substantial, that the Brazil Indians, while gathering the seed-vessels, place their young children on the leaves;—yrpe, or water-platter, they call the accommodating plant. But even these expanding leaves are not the glory of the Victoria; the glory is in the opening of the flower. We have sometimes looked in, for a passing moment, at the greenhouse, its dwelling-place, during the period of flowering—and then stayed for more than an hour, unable to leave the fascinating scene. After the strange flower-bud has reared its dark head from the placid tank, moving it a little, uneasily, like some imprisoned water-creature, it pauses for a moment in a sort of dumb despair. Then trembling again, and collecting all its powers, it thrusts open, with an indignant jerk, the rough calyx-leaves, and the beautiful disrobing begins. The firm, white, central cone, first so closely infolded, quivers a little, and swiftly, before your eyes, the first of the hundred petals detaches its delicate edges, and springs back, opening towards the water, while its white reflection opens to meet it from below. Many moments of repose follow—you watch—another petal trembles, detaches, springs open, and is still. Then another, and another, and another. Each movement is so quiet, yet so decided, so living, so human, that the radiant creature seems a *Musidora* of the water, and you almost blush with a sense of guilt in gazing on that peerless privacy. As petal by petal slowly opens, there still stands the central cone of snow, a glacier, an alp, a jungfrau, while each avalanche of whiteness seems the last. Meanwhile, a strange rich odour fills the air, and Nature seems to concentrate all fascinations and claim all senses for this jubilee of her darling. So pass the enchanted moments of the evening, till the fair thing pauses at last, and remains for hours unchanged. In the morning, one by one, those white petals close again, shutting all their beauty in, and you watch through the short sleep for the period of waking. Can this bright transfigured creature appear again, in the same chaste beauty? Your fancy can scarcely trust it, fearing some disastrous change; and your fancy is too true a prophet. Come again, after the second day's opening, and you start at the transformation which one hour has secretly produced. Can this be the virgin Victoria—this thing of crimson passion, this pile of pink and yellow, relaxed, expanded, voluptuous, lolling languidly upon the water, never to rise again? In this short time every tint of every petal is transformed; it is gorgeous in beauty, but it is "Hebe turned to Magdalen." But our rustic Water Lily, our innocent *Nymphaea*, never claiming such a hot-house glory, never drooping into such a blush, blooms on placidly in the quiet waters, till she modestly folds her leaves for the last time, and bows her head beneath the surface for ever. Next year she lives for us only in her children, fair and pure as herself. Nay, not alone in them, but also in memory. The fair vision will not fade from us, though the paddle has dipped its last crystal drop from the waves, and the boat is drawn upon the shore. We may yet visit many lovely and lonely places—meadows thick with Violet, or the

homes of the shy Rhodora, or those sloping forest-haunts where the slight Linnaea hangs its twin-born heads—but no scene will linger on our vision like this annual feast of the Lilies.—*Atlantic Monthly*.

Fuchsia Ricartonii.—There are many places in which this useful plant thrives remarkably well, not only in pleasure grounds and shrubberies, but also by the sides of walks in plantations. A gravelly bottom suits it best, but it ought to have a place specially prepared for it, say a pit dug out 4 feet wide and 18 inches deep; let the best of the soil be put in the bottom, as this Fuchsia will often root deeply if it finds congenial material in which to develop its roots. If in plantations it should occupy the most open positions to be found in them, and as Rhododendrons may be expected to adorn woodland walks during summer, this Fuchsia furnishes a profusion of flowers in the later part of the year. This variety of Fuchsia is much harder than many imagine, and where the sub-soil is sufficiently gravelly to give free passage to superfluous moisture to pass away, I have seen it grow into a great bush 6 and 8 feet high, and sometimes a healthy plant will throw up a shoot 6 feet long in one season. In exposed situations, or where the frost becomes very severe, it would be well to protect plants of this Fuchsia during winter. This may be done with Braken, and a few sticks driven into the ground to keep it from blowing away; if the tops are killed down by the frost in winter, young growths will push up from the root in spring.—G. DAWSON.

Prairie Roses.—Will any correspondent of THE GARDEN oblige by telling me what species of Rose is referred to in the following extract from *The Country Gentleman*?—INQUISITIVE. "No other hardy plant can show such a cataract of bloom, or display it with more elegance than these magnificent Roses. But they should stand well away from the eye, like an oil painting; and as for fragrance they have none to offer. The best position is against the wall of a back building, 100 feet or more from the front or chief point of view. The wall is convenient for support and spread, and the cool rich soil around and beneath the building secures luxuriance of growth. Red and white varieties planted together, as the Queen and Baltimore Belle, enhance the beauty of either, especially when distance lends enchantment to the view. That which mars their beauty, and the satisfaction of the culturist of these grand climbers, is the almost universal omission of seasonable pruning. All the old wood should be cleared out directly after blooming, just as is done with Raspberries after fruiting, and at the same season, about the first of August; the earlier it is done, the stronger will be the young wood for the next summer's bloom. All that is left will appear bright and growing, and, if neatly tied up, will delight the eye and fill the thought with expectations of a still finer, stronger, and brighter show next season, from the more numerous and better ripened fruit-buds and a freer flow of sap up the healthy young wood."

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Retinospora pisifera aurea.—The growth of this plant, which has a rich yellow compact foliage, is slow, and it bears clipping remarkably well. These qualities have suggested to us its substitution for Box as a garden edging. We accordingly made experiments, which have proved perfectly successful. We find that, as compared with Box (1) It is quite as hardy, and less particular in the choice of soils; (2) It is dwarfier, and bears clipping much better, as the leaves are very minute and dense, whilst Box leaves, from their size, get chopped up and mutilated by the shears; (3) It is far more beautiful, being of a lively golden colour, and very compact and leafy; (4) The cost per yard will not exceed that of common Box.—A. MORGREDDEN.

Double Primrose Culture.—A writer in the *Gardener's Record* mentions having seen, during the past season, a patch of double Primroses growing in an open and somewhat light soil, that generally suffered severely during the hot dry summer months. "Some clay, in the form of a thin layer, which could but be termed a top-dressing of clay, was laid over the bed to the extent of one-half, and the effect was remarkable. The plants growing amid the dressing of clay were of quite a vigorous character, while the others, not so treated, had a deplorable appearance. No doubt the Primrose requires to be kept cool about the roots, and the beneficial effects of this practice were quite evident in this instance." [This simply means that the Primrose, like many other wood and copse plants, suffers from having both roots and tops dried by the sun in an open spot, and that some kind of mulching will help to counteract one of these evil effects.]

Bedding Calceolarias.—In reference to Mr. Grieve's remarks about bedding Calceolarias (see p. 257), allow me to say that there has been in a garden in Torquay a splendid bed of Calceolaria aurea floribunda in full blossom since May, and it will continue until frost destroys the bloom. It consists of plants the produce of cuttings put in in October, 1872; they were bedded out the following May, but all through that summer they made but little progress, and several died though kept constantly watered. In the autumn they were taken up and planted much closer, and, as it was a mild winter, they continued growing, and became in May a dense mass of foliage and bloom, so that the sun never penetrated to the roots, which is the cause of so many dying in the summer. Should the weather be too severe for them to stand through another winter, the best plan for ensuring a good summer bed is to plant out the cuttings of this autumn very early in the spring, about 6 inches apart, they will thus be established before the sun is too powerful. Not one plant has died in the bed in question this year, but those that were planted in May, although very good large plants, dwindled away, and half of them have died.—W. F. T. Torquay.

ROCQUENCOURT.

From the ancient state of straight-lacedness—clipped trees and miserable harshness and monotony of French Gardens—a very notable change has long been taking place, both in public and private gardens. From the style of Versailles and St. Cloud, Sceaux, or the hundred other public gardens of the same school, to that of the garden parts of the Bois de Boulogne, the Bois de Vincennes, or the Parc Monceaux is a marked progress indeed. A similar change is observable in the private gardens, and there is in no country more charming oases of sylvan beauty than in French gardens made within the past twenty years. The old and rusty walls of clipped trees have rapidly given way before quick growing fringes of beautiful trees and shrubs; lawns, not always so fine as ours, are now much preferred to such stony and gravelly hideousness as one sees in the Grand Trianon, and, in short, a charmingly natural and refreshing aspect reigns where, in older days, a much less pleasing state of things prevailed. Among the most interesting of French gardens is that depicted in our illustration, originally formed and richly stocked by Madame Furtado. Here, when we visited it, might be seen some of the best features of modern French horticulture, and a few points were also observed which it may be well to refer to as things to avoid. We see, for instance, faithfully rendered in the illustration, the too abrupt slope round the piece of water. There is no greater evidence of want of true insight into landscape gardening, or into Nature, than that of forming stiff straight slopes, particularly by the margins of water. Given the desire, it is in all such positions easy to secure a naturally and pleasantly graded slope, which is as inoffensive to the foot and to the eye as the prettiest carpet of natural lawn that girdles the lakelet among the hills. Another evil well shown in the picture is the formal walk alongside the water. This is in most gardens easily avoided. There is no more certain way of robbing the margins of a fine piece of park or garden water of all natural grace than by forming such a walk around it. Having thus freely pointed out what appears to us to be blemishes, it is pleasanter to record that here is one of the finest examples of the excellent system of planting-out stove and other plants distinguished by leaf-beauty. Instead of the plants being staged in pots, as is mostly the case with us, they are planted on irregular rocky banks with walks winding between, and the effect is charming indeed. It shows conclusively, that we may get rid of much of the stiffness that obtains in our hot-houses without sacrificing any advantages of importance. The conservatory has an open central part planted with a bold mass of tropical vegetation, well-shown, as it springs from a carpet of Lycopodium as green as the freshest Grass, with tiny rivulets here and there; the two wings are devoted to specimen Camellias and other greenhouse plants, also arranged in a natural and pleasing manner. From the roof of a stove arranged in this way, the flowers of that gloriously-coloured climber, *Hexacentris mysorensis*, hung in abundance, producing a magnificent effect.

Open Spaces in the City.—A meeting of the inhabitants of Broad Street, London Wall, and neighbourhood, was held at Gresham House the other day, for the purpose of taking steps for the preservation as an open space of the garden belonging to the Drapers' Company in Throgmorton Street, Mr. Robinson in the chair. The chairman said several meetings had been held with the view of preventing the destruction of the garden and the erection of buildings on the site. Notwithstanding the representations made to the Drapers' Company, the trees in the garden had been cut down and preparations made for forming a road across it from Throgmorton Street to London Wall. Open spaces were necessary for the health of London, and although it had been asserted that the land in question was valued at £15,000 per year for building purposes, the health, happiness, and recreation of the metropolis were of far greater importance. Mr. Jenkinson thought the Drapers' Company might yield to the pressure of public opinion. He suggested that the representatives of the ward at the Court of Common Council should be solicited to bring the subject under the notice of the Court. After considerable discussion it was arranged that the Court of Common Council should be asked to keep up the ground as an open space or recreation ground, and to acquire it, either by purchase or agreement, from the owners.

THE GARDENS AT ROCQUENCOURT.

THE KITCHEN GARDEN.

PARSNIPS.

In some market gardens Parsnips constitute one of the principal crops, while in others none are grown. Where Parsnips do well, however, they are very remunerative. They require a deeply-trenched, free, well-drained soil. As a rule, market gardeners select a piece of ground for Parsnips that had been heavily manured the year before and cropped with Cabbages, Cauliflowers, French Beans, Celery, or similar crops, which had been cleared off in time to allow the ground to be trenched and ridged for at least a month prior to levelling it down for sowing. The variety almost universally grown is the hollow-crowned, a capital sort, that produces roots from 4 to 6 inches in diameter at top, and from 10 to 20 inches in length, and the crowns are, as a rule, buried a little below the surface soil. Preparatory to sowing, the ground is levelled, breaking the soil well in the operation, and finishing off by raking the surface smooth with a wooden rake, and sometimes rolling it. Shallow drills are then drawn for the seeds at about 18 inches or 20 inches apart; and, after being sown they are covered in by the feet or the back of a rake, and the whole is smoothly rolled. Sometimes, however, white or green Cos Lettuces are planted in rows at the above distances, and the Parsnips are sown afterwards in lines between them. In either case, Lettuces are planted—if not first, they are put in afterwards; and as the Parsnips take a long time to germinate, the Lettuces are removed before they injure them. The proper time for sowing is a much disputed point with gardeners, but nearly all agree that March is the best time. The market gardener, however, always makes a point of sowing Parsnips as soon after the middle of February as possible, provided the ground is moderately dry and warm, and crumbles freely when working it. The land is not manured for this crop; if it were, the roots, instead of forcing their way downwards perpendicularly, would ramify and become forked. The finest field of Parsnips I ever saw was one belonging to Mr. Bagley, of Turnham Green. The ground on which they grew was rich, deep, and rather heavy, a fault remedied, however, by continued manuring, working, and cropping. The year before this crop was put upon it, it had been heavily manured, and cropped with Cauliflowers, Lettuces, and Celery. After the Celery had been marketed about Christmas time, it was levelled, then trenched and ridged, but not manured, and in the middle of February, the soil being in fine condition, the ridges were levelled, and the seed sown in rows 20 inches apart. White Cos Lettuces were planted between the rows, and about a foot apart plant from plant in the row. The ground was twice hoed in a shallow manner between the Lettuces before the seeds germinated, and when the Parsnips were expected to appear, a man went over the plantation with a narrow iron-toothed rake, and raked the soil lightly over the rows, so as to dry and sweeten it, and to free it from lumps, so that the young plants might push through it easily. As soon as the Parsnips were fairly up and growing, they were thinned out a little, and after another short interval, they were again thinned, this time finally to 9 or 10 inches apart. The Lettuces were, when marketable, tied up and removed, and before they could choke or otherwise injure the Parsnips, which were now left sole possessors of the field. These soon grew apace, and received no further care than occasional hoeing; and, after they got too large for that, all the rank weeds were picked from amongst them. The roots made wonderful growth—so much so that, in many cases, a crack was visible along the line in which they grew. The bulk of roots from this field was enormous, many of the specimens measuring individually 7 and 8 inches in diameter at the shoulder, and 20 and 24 inches in length. It is injudicious to lift Parsnips for market before November, unless the demand for them is great and prices high, as they have not finished growing till that month. From that time until the middle of February, however, they are in fine marketable condition, and, being always left in the land where they grew, are lifted as required. Being thus left undisturbed, they preserve their flavour much better than they do when lifted and stored in pits—an operation which would

be both troublesome and expensive. Before growth begins, say, about the middle of February—every root is lifted, and, if not marketed at once, is stored in pits or sheds until a convenient season arrives for sending them to Covent Garden.

W.

RADISH CULTURE IN MARKET GARDENS.

The only varieties grown in the market gardens about London are the Turnip and Salmon or long-rooted kind, and the white and red varieties of both these sorts, the majority being red. These constitute the principal winter crops in the market gardens, the first coming in in the first or second week in December, the second three weeks later, the third in the second or third week in January, and others from that time till the end of March or middle of April, an interval of about three weeks elapsing between each succession. The empty space at command, the character of the season, the succeeding crops, and other circumstances, determine the number and extent of the Radish plantations. Where a great extent of land can be cleared and sown at one time, the sowings are fewer than when only a small space can be cropped, and where, on an average, four or five successive plantations constitute the number grown. Radishes do not grow well in summer, the weather being then too dry and parching for them; but, in a moist season, they may be grown even in summer with advantage. If the weather is moist a sowing is made in August on a cool piece of ground, and another a fortnight or three weeks afterwards. Radishes are usually grown on ground that has just been cleared from Vegetable Marrows, French Beans, Seakale, Rhubarb, or Celery. The first two crops are usually grown under fruit trees; by sowing time the trees are leafless, and whatever pruning they may have required will have been given them; they, therefore, do not shade the plants, but, on the contrary, shelter them a little, and before the leaves begin to grow in spring the Radishes are marketed. The ground, after having been dug or trenched, and manured, if necessary, is lined off into 4 or 5 feet wide beds, having 1-foot alleys between them. The seeds are then sown, raked in with wooden rakes, and also slightly covered from the alleys, and rolled. About three inches in depth of rank litter are then strewn over the beds, and left there until the seedlings appear, when, if the weather is fine, and not very frosty, they are uncovered during the day time, and covered at night; but, during hard, frosty, and snowy weather, they are kept covered, even during the day-time. All the sowings are treated in the same manner as regards covering and uncovering; and, after the middle of February, if the plants are strong and the weather mild, the coverings are dispensed with, but kept in the alleys in case of emergency. Radishes, in their rough leaves, will stand a few degrees of frost with impunity, if the ground is not very wet. In April, the litter used in covering is removed and built into a large stack, to be converted into manure. The March and April sowings require no covering. Birds are very destructive to Radishes, from the time of sowing until the plants have made rough leaves; they eagerly devour the seeds before they germinate, and look after the husks after the seedlings appear, pulling up the young plants to effect their purpose. In order to counteract this mischief, boys are kept to watch and scare away the birds. In March the first out-door Radishes are fit for market, the largest being pulled up first, leaving the others for a week or two later in order that they, also, may become marketable. When drawn, they are tied into little bundles, bound round with a wythe, or piece of bast, washed after being bunched, and packed into baskets for market. After Radishes, may be planted Seakale and Lettuces, Cauliflower and Lettuces, preparations being made for Celery, Beet, Vegetable Marrows, French Beans, or any other crop suitable for the situation. Autumn Radishes are treated in the same way as those for spring use; but, as I have stated, the litter coverings are not used except in the case of hot dry weather. When Radishes are wanted earlier than those of the December out-door sowings, they are obtained from gentle hot-beds, made up about the 1st of January. These hot-beds are of two kinds—one the common frame hot-bed, the manure being in sunk

trenches; and the other merely a sunk bed of manure, covered with a few inches of soil, and mulched over, like the out-door beds. P.

Box Edgings.—Nothing, in my opinion, beats a good Box edging, either for the kitchen garden or for the most elaborate geometrical designs; but there is such a vast difference in the appearance of Box edgings at different places, that possibly a few remarks in reference thereto may not be unacceptable. In the first place, they must be clipped every year, and it is on this operation, and more especially on the time of year on which it is performed, that the appearance of the edging for the rest of the year depends. After repeated trials of clipping at different seasons, I am confident that the end of May or the first week in June is the best time for performing this operation, and for the following reasons, viz., that, although the Box is such a hardy plant, its young growths often suffer from spring frosts during May, and, by clipping at the time named, all irregularities of surface are removed; the young growth commences again immediately, and takes off that "straight-faced" appearance that always follows the use of the garden-shears. The young growth gives the edging a pretty appearance, and becomes thoroughly matured to stand any weather during the ensuing winter, which is not the case when clipping is deferred until the end of summer. The operation, although simple in itself, requires some considerable experience before it can be performed properly. For straight edgings, of whatever length they may be, we invariably stretch a line the whole distance to indicate the centre; then we take the desired width off either side, and level off the top with long clean cuts made by sharp shears. I have seen edgings laid in in almost every month in the year, and, with attention to watering, they have almost invariably succeeded; but I never saw them present an inviting appearance when the above date for cutting was very widely departed from. The greatest amount of injury is generally done through salting the walks to destroy weeds, when a heavy fall of rain floats the salt to the edging, thus most effectually destroying it. The next worst enemy to Box edgings is the foliage of garden crops or flowers overhanging them, and drawing them up weakly and blanched, so that they cannot withstand severe weather. Wheeling or treading on them also destroys them. Where proper attention, however, is paid to Box, the effect produced by it soon banishes from gardens all its so-called rivals.—JAMES GROOM.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Sutton's King of the Cauliflowers.—I have this season grown Walcheren, Early London, Vetch's Autumn Giant, and Sutton's King of Cauliflowers. The first two, literally speaking, burnt up, but the King and the Giant withstood the drought well. With me the Giant has always been rather coarse, even in a small state; while the King is a very delicate vegetable, equally large, and, in my case, larger than the Giant. I must, therefore, ask your readers to grow both and judge for themselves. I may add that these two varieties are very hardy, and certainly the best for a dry summer.—R. GILBERT.

Onion-fly. G. W. BERNETT. The grubs which attack your crop are the larvae of the Onion-fly, *Anthomyia ceporum*. It is very difficult to destroy them. Strew the beds with powdered charcoal, and pull up and destroy all that are affected, before the flies become developed.

Clabbing.—In the gardens at Streatham there is an unusual amount of clabbing at the roots of Cabbages, Broccoli, &c., this year: can you suggest a remedy?—SYMA. [The usual remedy, or rather preventive, is putting wood ashes in the holes along with the plants at planting time.]

Good Potatoes: H. KILLINEY. Hogg's Early Goldstream, Rivers' Royal Ashleaf, Daintree's Seedling, Paterson's Scotch Blue, Wheeler's Milky White, Waterloo Kidney, Haigh's Cobbler's Lapstone, Pebble White, Edgecote Second Early, Rector of Woodstock, York Regent, and Yorkshire Hero.

Truffles.—Is the accompanying Fungus the true Truffle (*Tuber cibarium*)? I found it growing here under several of the Conifers.—A. B. [Your Fungus is *Melanogaster analogus*, a sort of Truffle. It differs from true Truffles in having the sporidia borne on spicules instead of being carried in asci.—W. G. SMITH.]

Liquid Manure.—The best is that from sheep or deer droppings. Put 2 or 3 bushels of manure in a basket, and plunge it in a tub or tank of water; the basket is to keep the sedimentary parts of the manure from mixing with the water. A better way still is to have a slate tank divided in two parts, and several layers of filtering gravel, &c., on one side, as described and illustrated in THE GARDEN, Vol. I, p. 220.

Mulching.—For a general mulch, there is nothing beats the soil itself. A thorough and frequent pulverisation of the surface a few inches down is the same as a coat of saw-dust, cut straw, or any similar fine application. Our corn fields, therefore, are mulched to advantage by the use of the cultivator. The mulch, if a thick one, will keep all beneath moist, and prevent weeds and the crusting of the surface, thus giving access to air, and keeping the ground cool. A good mulch for shrubs and young trees of all kinds, is one of green Grass, applied immediately after the last stirring of the soil, and sprinkled well with leached ashes. The ashes will draw moisture from the air, and help to protect the soil below. This, also, will add fertility. We have used it for several years with the most gratifying results. The severest drought has but little effect; there is a fine growth, seeming in defiance of the weather.—T. U.

Pyrethrum Insect Powder.—The commercial insect powder is very liable to failure, but a powder prepared as follows from the same plant (*Pyrethrum roseum*) is, according to the *Florist*, most effective against moths, fleas, bed bugs, and poultry vermin, and, when administered in a weak infusion, is also a useful internal remedy against worms. Seeds of the *Pyrethrum*, which are obtainable from large seed dealers, are to be sown in May, not too thickly, in a well-cultivated bed, and, if the weeds are kept down, will develop into strong plants by the autumn, although they seldom bloom before the next May or June. The flowers are to be plucked as they become fully developed, and the yellow disc-flowers separated from the red ray-florets, thoroughly dried in the shade, and finely pulverised. Flowers can be plucked even in the autumn, so that a few plants will produce a considerable quantity of the powder. As the plant is perennial, it can be propagated by division, and since it is indigenous to the Caucasus, it is not damaged by a low winter temperature.

The Turnip Caterpillar.—I beg to inclose you specimens of a grub having a most peculiar liking for young Cauliflower and Cabbage plants. The stem of the plant is so completely eaten through that the head falls off, and the insect may be found buried in the soil close to the plant. The insect is so very destructive that I am curious to learn its natural history, and whether there is any other mode of destroying it besides catching and killing it.—H. EVANS, Swindon, Wilts. [The caterpillars are those of the Turnip moth, *Agrotis Segetum*, the life history of which, illustrated with figures, is given at p. 320 of Newman's "British Moths." It is the most destructive of all British insects, the Turnip fly not excepted. The egg is laid in June, either on the ground or on some plant, generally a seedling, close to the ground. Hatched in this situation, the infant caterpillar is enabled to attack the young Turnips, Carrots, Cabbage plants, Charlock, Mangold Wurzel, Radish, and also a number of the common weeds. Having tried the caterpillar with a great variety of provender, Mr. Newman says he can vouch for its feeding on any plant sufficiently succulent. When young its depredations are mostly about the surface of the ground, and it seems to delight in that particular part of a plant which lies between the root and stem; great numbers of young Turnips and Carrots are divided at this spot, the upper part being left to perish on the surface of the ground. It also visits our flower gardens. Very often in a bed of China Asters, that old-fashioned but still favourite flower, the leaves of a plant here and there will be found withering and curling up, and you become perfectly aware that it is dying, and cannot tell why. Just examine the stem where it enters the ground, and you will find it decorticated; the rind has been gnawed off all round, and the circulation of the sap being prevented, life is extinct. You probably pull up the Aster, expecting to find the enemy, but fail; his depredations were committed in the night, and before daybreak he has wandered away several inches, perhaps feet, and has burrowed like a mole in the light friable earth that gardeners love. It is tedious work looking for the mischief maker with candle and lantern, and picking up every caterpillar, and it is destructive to dig between the plants. Some gardeners, after becoming really acquainted with the enemy, sprinkle lime on the ground, others sawdust, others soot, others salt, others ammoniacal-water from the gas-works; but the result is uncertain and unsatisfactory. Among Turnips the havoc made by these grubs is awful; in September they burrow deep in the earth, and attack the bulb at the very base just where it becomes a tap root. Here they excavate large cavernous holes in the Turnips, and in these they henceforth reside, not returning to the surface until the supply of food is exhausted and the Turnip reduced to a mere shell, full of their excrement, and putrifying.—Ed. Field.]

Introduction of the Mulberry.—Mulberry trees were introduced into England, early in his reign, by James I., who spent £935 in planting them near his palace; and by royal edict, about the year 1605, offered packets of Mulberry seeds to all who would sow them, for the purpose of encouraging the cultivation of silkworms for the promotion of silk manufacture in this country. The royal patronage rendered the tree so popular that there is scarcely an old garden or gentleman's seat, which had existed in the seventeenth century, in which a Mulberry tree is not to be found. In 1609, Sienr de la Foret, who had in France a nursery of 500,000 plants, travelled over the midland and eastern counties of England for the sale of Mulberry trees, and distributed not less than 100,000 trees.

Sensible to the Last.—A strange legacy of 1,000 dollars is left to the Reformed Church at Peapack, New Jersey, by the will of Jacob J. Tiger, deceased, upon condition that the church grounds be kept free from Canada Thistles and Wild Carrots, and if the growth of such foul weeds is permitted to any extent, then the legacy is to be forfeited.

THE ARBORETUM.

THE JAPANESE PLUM.

(*PRUNUS JAPONICA*.)

This bears handsome rose-coloured double flowers, and has a dwarf branching habit; the leaves are oblong-elliptical, acuminate at the point, and finely and regularly dentated; the flowers, which resemble miniature Roses, appear about the beginning of April, and are succeeded by small, but rather pretty-looking, fruit, hung on slender foot-stalks; it is somewhat heart-shaped and rounded at the top, terminating in a hard thorny bristle; its skin is a deep red wine colour, smooth and glossy; the flesh adheres to the stone, and, when ripe, is pulpy and melting, and of a violet colour; its taste is not sweet—on the contrary, it is sourish and astringent; the plant

The Japanese Plum (*Prunus japonica* or *sinensis*).

fruits even when it is very small. An open light soil, slightly humid suits it best. It may be increased by means of cuttings, grafting, and budding.

ON INSECTS WHICH INFEST CONIFERÆ.

By ROBERT HUTCHISON.

THE insect world, with its teeming myriads of devouring creatures, varying so infinitely in habits, instincts, forms, and organs, is principally distinguished as to its functions, which may be said to be discharged with a view to great and general benefit and utility to the numerous species themselves, as well as with the object of destroying or removing nuisances which would otherwise deform or possibly infect the earth and its inhabitants. Many insects may, indeed, be said to be the earth's scavengers, the pruners of Nature's too luxuriant productions. But while a counterpoise is thus established and maintained for the purpose of checking any tendency to overgrowth in the vegetable kingdom, it not unfrequently happens that by the same agency the projects of man, in regard to the cultivation and use of many staples of vegetable economy, are frequently seriously interfered with, and sometimes altogether marred, by the predacious and destructive attacks of many of the species of this great division of the animal world. The study of entomology, and the consideration of its classification into (1st) insects which are beneficial to the growth of plant life by destroying others in their larva state, which would prove, if unchecked in population and distribution, most injurious to many trees, shrubs, and plants; and (2nd) insects which are themselves parasitical and inimical to the health and development of vegetable life in many forms, is a subject of the deepest interest to the close observer of Nature, and especially so to the student of arboriculture, as well as to every lover of forestry who is practically engaged in that all-engrossing occupation. It is with the insect world, in the latter of the two sub-divisions to which we have referred, that we purpose now to deal, and attention will be mainly confined in this paper to the most prominent and most popularly known species which attack Coniferous trees, and ravage

no less seriously the newer introductions of this family than they do our common Scotch Fir and other older and more commonly planted varieties of Conifera. It has been universally observed that trees of the Pine tribe, most frequently affected in their young stage by the attacks of insects, are those which are planted in soil previously cropped by the same description of trees. This will also be the case even although the previous crop may not have been affected in the least degree by such ravages, thus clearly showing that the cause of the destruction to the second crop does not lie in any sort of infection or transmission of the disease (if so it may be called) from the former occupants of the soil, but rather from the growth and establishment of larvæ in the ground itself, engendered probably by the dry condition of the soil caused by the previous cropping and absorption of the moisture by the numerous roots left in the ground after felling. This theory is supported by the fact, that frequently after thinning young Fir plantations insects are observed to attack a district where they had not been previously known. Probably the dried nature of the substratum of soil, intensified by the continued absorption of moisture by the old roots left in the ground, and also by the sprouting of some of the hardwood stools, may afford congenial habitats for the incubation and increase of these obnoxious enemies to the Fir tribe. Some authorities attribute the appearance of insects in such cases to the harbour afforded to the little animals in the decaying stumps, and to the weakened growth in the young wood of the trees left in the plantation from the diminution of moisture in the soil; but it appears more probable that the real cause lies in the drier state of the soil itself (independently of the thinning process), affording a suitable and congenial site for the base of the operations of the insects, rather than in the harbour afforded to them by the decaying stumps of trees thinned out. Thinning tends to produce stronger instead of weaker shoots of young wood upon the survivors, and the roots of trees felled will remain for a year or two in a sound condition, whereas the attack of the insects upon the plantation generally commences almost simultaneously with the process of thinning. In further support of this proposition it may be stated that in any wood where the attacks of beetles or other insects are observed after thinning, it will be found that, if there happens to be a wet bit (*i.e.*, a part less well drained than the rest), the trees there are happily exempt from the inroads of the invaders during the earliest stages of their attack. A careful observer of forest economy has already observed this fact in his own experience.* Another fact worthy of notice here, and to which particular reference will be made hereafter, is that these marauders of Coniferous plantations seem greatly enamoured of the cut and drying twigs and branches from early prunings or thinnings. It has been frequently observed that they prefer locating themselves among these cut branches to any other shelter or cover, so long as they find them in a fresh, although drying, condition; and they will invariably settle on them rather than on any part of the growing trees themselves. This predilection for shoots in a semi-dry or half-withered state is further attested by the circumstance that insects which attack the Fir tribe invariably commence upon a subject already evincing indications of sickness or decay. This is apparent in woods where no pruning or thinning has afforded them an opportunity of selecting their favourite haunts among felled branches and stools, and in the absence of such they are universally found to select apparently sickly specimens in preference to very robust and healthy plants, the juices of luxuriant and vigorous growths being probably too strong and rank in their vitality for their slower insect development and economy. One explanation of this generally observed preference of insects of various orders for diseased or sickly specimens of the trees they prey upon, is given by M. Andouin, Professor of Entomology in the Museum d'Histoire Naturelle at Paris, who has closely studied and noted the habits of many insects, and there appears to be good ground for accepting it as authentic and reliable. He thinks that the quasi-incipient decay of the tree is due, not to any inherent failure of the plant-life of the specimen, but to the attacks and boring operations in the bark of the tree caused by the search of the male insects (chiefly) for food, which injures the bark, inducing an unhealthy foliage; into these sub-cortical borings the female deposits her eggs; and so what we usually ascribe as the primary cause of the tree's sickness is merely the secondary result of the creature's operations, which are really an attack, in the first instance, upon a healthy tree for food. These borings weaken and exhaust the functions of the bark, whereupon the female deposits her eggs in the previously made workings of the male insect, while the act of burrowing and depositing the eggs and of so injuring the tree are commonly supposed to be confined only to trees which previously evinced signs of decay. In the *Review Entom.* (iv. p. 115), Silbermann also states, upon the authority of Dr. Ratzeburg, that the large weevil (*Pissodes notatus*) attacks the bark of young Pines with its trunk, and thus renders the trees unhealthy, prior to the female depositing her eggs

* W. Tivendale, Scott. Arbor. Soc. Trans., vol. vii. p. 89.

in them. The modes of insect attacks upon Coniferous trees may be directed towards the root, the bark, or the tender young shoots; but, in any case, their preference for the apparently weaker growths and constitutions holds good, whatever may be the method of attack, and whether their victim be a recently planted seedling or a mature tree. They probably, in the first instance, feed on their prey, and then breed in the cavities which their predacious attacks have made.

Season in which Insects are most Injurious.

The season when insects are most injurious to Coniferous woods is generally from the beginning of April to the end of June, and again from about the beginning of August till the middle or end of September, in favourable and mild weather or ordinary seasons. Of course, cold or wet weather may affect their operations; but, as a rule, these are the times of the year during which the greatest havoc is committed. Hot and dry summer weather, especially if succeeded by a cold, dry, frosty winter, favours the dissemination and increase of forest-feeding insects. The warmth of summer fosters their breeding, because by its genial influence their period of transformation from the larva state is shortened, and abundance of time is afforded for several broods to mature in succession; and, when the following winter is dry, a superabundant number of insects will be found in the ensuing spring; while, on the other hand, should the summer season prove wet and deficient in sunshine, and the following autumn and winter be damp, intensely cold, or snowy, the numbers of insects, whose increase had been previously checked by the adverse summer, will be materially lessened in the following spring, and the destruction to the woods for the time will be proportionately less severe. These remarks principally apply to insects which affect the bark of Pines, especially the Silver Fir (*Picea pectinata*), and confine their attacks to the tree through that medium, selecting chiefly those old trees the bark of which is not very hard. They direct their attack, in the first instance, to apparently weakly or dying specimens, or settle upon felled timber, feeding upon the stagnated sap of the inner bark, to which they bore, by the aid of their sharply-toothed jaws, in a direction slanting upwards as far as the sap wood, and from thence the female hollows out a perpendicular canal about 3 or 4 inches in length in the inner bark, with small niches close together on each side; in these she deposits her eggs, which are small round white objects, and, having covered them up with a slime of her own secretion, the larvæ are hatched in about fourteen days, and they again cut for themselves ramifying passages in all directions, which widen as they proceed, and resemble alphabetical letters in appearance, whence the insect has sometimes been popularly styled the "Typographer Beetle," or *Bostriichus typographus* (Fabricius). Should Silver Firs be scarce in the plantation, or the insects be so numerous as to overrun all the trees of that species, they will next attack any other Fir or Pine that may be most convenient. The full period necessary for the development of this mischievous little creature is about eight weeks from the egg to the full-grown beetle, and there are generally two broods in each season, the last sometimes remaining (owing to cold or wet weather) concealed dormant under the bark of the tree till the following spring, when they are fully developed. The injury to the Silver Fir by this insect will thus be seen to be effected by the destruction of the sap-wood, which every arborist is aware will ensure the speedy death of the tree, even when otherwise perfectly sound and luxuriant. A short description of this most destructive insect may here be interesting. It is, when full grown, a beetle of from 2 to 2½ lines long, and about 1 to 1½ lines broad, and hairy. On its first development to the perfect state, and while still under the bark, it is of a rusty yellow colour, becoming darker by degrees, and upon its escape to the open air is of a brownish-black; jaws, sharply toothed; eyes dark brown; wing-cases, deeply punctured, broader behind, deeply and obliquely impressed; the impressions with crescent-shaped margins, which have from 4 to 6 irregular teeth. Thorax and sternum always darker than the wing-cases. The female is distinguished by a thicker abdomen, and is less covered by the wing-cases. The larva or maggot is 3 lines long, wrinkled and white when it leaves the egg, soon becoming yellowish at the head; the back reddish striped; jaws, sharp; antennæ, short; feet, six in number and yellowish. The nymphs or pupæ are white and soft at first, becoming harder and yellower by degrees; they are almost the form of the beetle, only with pale indications of the wings, and with the feet drawn up under the body.*

Bark-boring Insects.

The bark-boring order of insects are not only very numerous, but they are probably, from their mode of attack, the most destructive of all to whose ravages the Pine family are liable. Not only is their process of destroying the inner bark and alburnum very detrimental to the tree, but the myriads of little cell-holes which they cut in the

bark, even if their further operations be suspended or prevented, interrupt the course of the descending sap, and admit the percolation of rain and other ungenial weather, which causes the bark to peel off, causing permanent injury to the tree. These bark-burrowers belong principally to the family of Scolytidae, including the genera *Scolytus*, *Hylesinus*, *Hylurgus*, *Tomicus* (*Bostriichus*), &c. They may be distinguished into two classes, viz., those that bore into the heart and body of the trunk of the wood, and those that confine their inroads to the inner bark with its adjacent sap-wood or alburnum. Probably in the case of Coniferous trees, the operations of these internal wood-borers are chiefly of the latter description; while there are many insects which attack hardwood timber, and do not confine their inroads to the inner bark, but chiefly burrow into the heart of the trunk itself, rendering even large Willows, Poplars, Oak, Elm, and other timber trees so hollow as to be easily blown down. Of these destructive creatures are the stag-beetle family (*Lucanidae*); and the very widely-branched tribe of Capricorn beetle, including *Prionus*, *Cerambyx*, *Lamia*, *Stenocorus*, *Leptura*, *Rhagium*, *Gnomus*, *Saperda*, *Callidium*, and *Clytus* (Fab.) Nor are the ravages of these mischievous creatures apparent and important in the forest and plantation alone, but very frequently the doings of some of them only become known in after years, when trees apparently sound have been felled and converted into timber for construction purposes. This is owing to the length of time sometimes necessary for the full development of the larvæ of many of the species. For example, in the order of Hymenoptera, one genus called *Sirex* is peculiarly destructive to Fir timber. In woods in Yorkshire, Stephens reports that whole plantations of Firs have been known to be destroyed by the operations of its larvæ under the bark. Two of the most conspicuous and destructive members of this genus are *Sirex gigas* and *juvenis*, both of which have been known to issue from the wood of joists and flooring in houses, after the timber had been wrought up and used for three years. The other principal bark-boring beetles which affect Coniferae are *Tomicus pinastri*, *Laricis*, *Micographus*, *Typographus* (already referred to), and *Chalcographus*, which are happily, however, less known in Great Britain than in the Continental forests. We have, however, more common in this country, the well-known *Hylurgus piniperda*, and the two large weevils, *Pissodes notatus* and *pini*.* Another secondary ailment, which frequently befalls the victim of these bark-destroying insects, arises from the permanent disruption between wood and bark caused by the innumerable earwigs, spiders, flies, wood-lice, &c., which take possession of the cavities, allured by the exuding sap, no less than by the shelter which the loose bark affords. We have in Scotland little conception of the damage done to forests by these insects. Numerous instance are on record of the extent of their prevalence and ravages. In Germany and Austria, for example, it is stated that 80,000 of the *Bostriichus typographus* have been found in one tree; and so great is the vitality of this little pest that nothing short of fire will destroy it. In the beginning of last century it was unusually abundant in the Hartz forests, and continued in immense numbers for several years—first in 1757, when its ravages were very severe; again in 1769 and in 1783, when the total number of its victims in the forests mentioned amounted to 1,500,000; and the indirect result of its destructive agency was that the industrial pursuits of the surrounding country were seriously crippled, and in some localities actually suspended. Cold and wet seasons, however, in 1784 and in 1789, tended greatly to diminish its numbers. In 1790, however, it reappeared, and again in 1796, when serious fears were entertained for the safety of the few remaining Fir trees, which the ravages of former years had spared.†

Foliage and Root Destroyers.

But in addition to the insects which infest Pines by burrowing under the bark, there is an equally numerous and destructive host, whose ravages are carried on with similar precision in other ways, by attacking the foliage or the roots of the tree. The well-known substance termed "honeydew," is said to be the secretion of a species of aphid. The Larch in this country is infested with an aphid, whose wax-like "cottonty" filaments are well known, and are often so abundant as to whiten the entire tree, and ultimately (if not removed or checked) to cause its destruction. Then again, there are other deposits caused by the aphide, which, although in themselves very beautiful, resembling as they do, when their mechanism is closely examined, fruit, blossoms, flowers, &c., are yet, if allowed to spread to undue proportions, full of danger, and sometimes convey total destruction to the tree. These deposits refer to the secretions of the *Aphis abietis*. The larvæ of several moths also attack Fir and other trees by destroying their foliage, viz., *Dendrolimus pini*, *Psilura monacha*, *Achatia piniperda*, *Bupalus piniarius*, *Orthotania turionana* and *resinella*, &c. The three species of saw-fly (*Lophyrus pini* and *rufus*, and *Pamphilus erythrocephala*) tend further to swell

* Kollar on Insects, London's Translation, p. 358.

* This insect is said to be common in Rumania. † Latreille, Hist. Nat. iv, 194.

the number of the enemies of the Pine tribe, no less by their annual destruction of the leaves of the year, than by their pertinacity of attack, causing the unfortunate tree to draw upon the undeveloped resources of the next season's supply, to make up the deficiency thus caused in the present. This process, if repeated for a very few years, certainly terminates fatally for the tree. The ravages of the insects we have just referred to are, however, chiefly confined to the Continent of Europe, while in Great Britain their attacks, although they have been noticed, are not as yet to any great extent frequent or urgent. They have certainly been known to exist in Great Britain in several localities, but many of them appear not to be indigenous, so it may probably be assumed that their larvae have sometimes been imported, either with seed or upon plants from the Continent. As some of the varieties, such as *Pissodes notatus* (Fab.), already referred to, have of recent years become more common in the United Kingdom, it is probable that it has thus been introduced. This remark applies also to *Acanthocinus ædilis* (Linn.), a little mischief-worker, called in some districts "the timber man." Thus we see that there are many species of insects whose destructive propensities are confined to the leaves, bark, and shoots of the Fir tribe, but there are also others, whose operations are directed to the annihilation of the seeds and cones. These are devoured, whether ripe or unripe, with great avidity. To this class belong *Eupithecia togata* (Hb.), whose larvae are very destructive to the dried seeds of Scotch Fir, the *Phycis abietella* (Za.), which, in addition to tunnelling into the cones of *Pinus sylvestris*, *Pinus maritima*, and other Firs, and destroying their vitality, lodge themselves in the decaying wood of the tree, and thereby hasten the process of dissolution. The colour of all these insects at one period of their existence, so closely resembles the bark and other portions of the tree, that their detection is exceedingly difficult. Indeed, so well is their presence concealed by this means, that their existence upon the tree attacked is first known by numerous spots of resin being seen oozing from the bark. If examined carefully, each of these spots will be found to cover a small aperture, in which the insidious enemy has securely located himself. In this manner, whole trees, and ultimately, entire plantations, are overrun and seriously damaged. The list of those insects which attack roots and subsist upon them, is fortunately less numerous and important. Their ravages are chiefly directed against dead and decaying roots of coniferous trees. The best known of this class is the *Hyllobius abietis*, which may be taken as the type of the whole. It is one of the largest of the British Curculionidae, or weevil family.

The *Hylurgus piniperda*.

The destruction caused to Pine plantations in this country by the attacks of the *Hylurgus piniperda*, and the wide area over which (both in England and Scotland) it has been observed, demand more than a passing notice in a paper like the present. It is very commonly found upon the Scotch Fir and Weymouth Pine (*P. strobus*), and many other Conifers, detracting oftentimes by its ravages from their deservedly admired, picturesque, and interesting appearance. This beetle belongs to the same family as one whose attacks upon the common Elm (*Ulmus campestris*) are well-known in Scotland—namely, the "*Scolytus destructor*," whose ravages upon the Elms in St. James's and Hyde Parks, London, created some years ago considerable interest and attracted public attention. The injury done by the *Hylurgus piniperda* consists in its destruction of the leading shoots of the Fir or Pine which it attacks. It is incessant in its operations when these are fairly commenced, and the following narrative of the mode and progress of its attack, by Mr. John Lindley, will give an accurate idea of the rapidity and devastating effects of this insect's operations. "For the purpose of observing its proceedings more narrowly," says Mr. Lindley, "I placed a shoot of the Scotch Fir under a glass with the insect. In about three hours after, it had just begun to pierce the bark at the base of one of the leaves; its mandibles seemed chiefly employed, its legs being merely used as a means of fixing itself more firmly. Four hours after, its head and thorax were completely buried in the shoot, and it had thrown out a quantity of wood, which it had reduced to a powder, and which nearly covered the bottom of the glass. In sixteen hours more it was entirely concealed, and was beginning to form its perpendicular excavation, and was busily employed in throwing back the wood as it proceeded in destroying it. There were evidently two kinds of this sawdust, part consisting of shapeless lumps, but the greater portion of very thin semi-transparent lamellæ, or rather shavings, which presented an invariably regular spiral appearance. I now examined it every day till the fifth, when I found it had emerged through the central bud at about an inch from where it had first commenced." Of this most destructive pest there are several varieties well-known throughout the United Kingdom, which may be specified as follows:—*Hylurgus piniperda* (Linn.); *H. rufus* (Mars.); *H. obscurus* (Mars.); *H. picus* (Mars.); *H. angustatus* (Gyll.)=ator

(Mars.); *H. rhododactylus* (Mars.); *H. ater* (Fab.)=niger (Mars.); *H. Boleti* (Mars.). They are found principally in June, July, and August, under the bark of the trees they have attacked. Hitherto it seems to have been the general opinion that they molested only diseased or decaying and feeble trees. Some authors even assert (Selby amongst others), that in no single instance have they ever been known to attack a tree in perfect health; but this point we have already referred to in this paper, and we think it is conclusively shown, from recent observations of their habits, that, in their incipient stages of attack, so insidious are their movements, that it is only after a time their presence is detected and then the vigour of the tree has already begun to decline, and thus the insect is assumed to be the result rather than the cause of the tree's failure.

Other Insects Injurious to Conifers.

As it would be impossible within our prescribed limits to describe and specify all the insects which are injurious to the Pine family, or whose ravages tend to retard the progress of that interesting class in our gardens and arboreta, we can only name a few others whose predatory habits are well known in certain localities, before passing on to notice some of the means of prevention which appear at least feasible, if not thoroughly effectual, for the prevention of the progress of the mischief which these animals occasion. In some situations the *Ernobius mollis* (Linn.) is frequently found upon both Scotch Fir (*P. sylvestris*) and *Pinus maritima*. Like the *Hylurgus piniperda*, it lives at the expense of the tree; but Perris (a French naturalist) asserts that it only attacks sickly or ailing plants. To this, as has already been stated, we object, and need not recapitulate the reasons. *Blastophagus piniperda* (Linn.), *Hylastes ater* (Payk.), and *Hylastes palliatus* (Gyll.), which in some places is very abundant, are all extremely destructive. One of the most fatal enemies of the Silver Fir (*Picea pectinata*), and which is to be feared is increasing in many parts of the country, especially in low-lying situations and in deep or heavy soils, is the *Bostrichus typographus* (Fabr.). This insect confines its attacks to the leading shoots of the tree. These it disfigures by settling upon their bark, and sucking the juices of the plant till the young wood is literally killed. It spreads with marvellous rapidity over whole trees, and frequently causes total destruction to every young Silver Fir in a plantation. Young thriving trees of about 8 to 20 feet in height appear to be most vulnerable to its attacks. The first appearance of the tree being infested with this plague is to be noticed upon the main stem and underside of the branches and young shoots, where it presents the appearance of a pure white minute substance in small patches close together, which, when microscopically examined, are found to consist of an adhesive cotton-like substance or covering, within which numberless clusters of the eggs of the creature are deposited, and occasionally the insect itself may be found. Gradually the whitened appearance spreads, and with wonderful rapidity the entire bole and branches seem to be dusted over with this downy matter, containing myriads of animals, each busily engaged with its sharp, though minute, proboscis in tapping the juices of the tree. Their settlement upon any tree will continue for two or three years, till, from first presenting a dwindling and unhealthy look, the unfortunate victim falls into a decline from which Nature cannot recover it. The spectacle presented, as the progress of decay proceeds, is indeed melancholy; the top branches and terminal shoots die first, and gradually, tier by tier, the handsome branches whither off, and in a very few seasons the tree is killed to the ground-line. This insect never attacks the leaves, but confines its ravages entirely to the bark of the young shoots and bole. A nearly allied species of *Bostrichus* (*B. laricis*) is very common upon the Larch. It does not, however, prove so fatal in its attacks. This insect is commonly and appropriately called "the Larch blight," from the appearance which it gives the tree when first attacked. The eggs may easily be detected concealed in the crevices of the young bark, and in the hollows around the buds, where they abound in winter time, and are easily discernible by the naked eye, like minute round black grains. They propagate in spring with marvellous rapidity, covering leaves, branchlets, and stem with a small black covering, which gradually whitens as those creatures weave, for a covering and protection from rain, a thick, white, viscid, woolly-like substance from their numerous pores, and which is the cause of that sticky and clammy feeling so well known in connection with the Larch tree. Happily, as has already been stated, the ravages of this little creature are seldom fatal, although it lives upon the juices of the plant, sucked out by means of its sharp proboscis, and according to the moisture and temperature of the season are its attacks more or less severe. For instance, if, by reason of unpropitious frosty winds in spring the opening foliage of the Larch should suffer a check, the trees so affected are more likely to be overtaken by the subtle and interminable exertions of its army of little enemies; and after such a season the Larch trees present a sicklier hue, and

have a more viscid feeling, than in a season when their vitality has flowed in an unchecked tide into a rapidly-developed foliage and blossom.

Insects Beneficial to Conifers.

But while thus presenting the dark side of this picture of Nature in her forest economy, it should also be borne in mind, that although a long catalogue of most destructive little insects has been named, there is also a very numerous class of insects which are not only not detrimental to the Coniferous or even hardwood trees, but are directly beneficial to them, and especially to the Pine tribe, in destroying, and thus keeping in check, other insects which are in themselves destructive, and many of which have been named in the foregoing pages. For example, in the United States of America, there exists a small black lady-bird, with two red spots on its wing-covers, named *Chilocorus bivulnerus*, which is remarkably useful in destroying bark lice and Pine-tree scale. Another small lady-bird, *Exochomus gnexi*, which is of a red colour, with two black spots on its wing-covers, and of similar habits, is also frequent, and deserves protective attention. Many of the ichneumon flies destroy whole acres of caterpillars infesting Fir trees; and without the aid of such small predaceous and parasitic allies, destructive insects would increase to such an extent, as to render all forest labour unavailing. It is well known, that while there are multitudes of noxious insects devastating whole forests, there are also many useful little animals, which by their operations may be said to act as the good genii of all trees, and chiefly of the Coniferous tribe. By diminishing the numbers of the injurious, they check their otherwise too rapid increase; and it is the more necessary to state this fact prominently, because, while the planter sees only the damage which is done by the obnoxious creatures, he seldom observes those little insects and their operations which, unappreciated because unseen, are silently, but not the less surely, engaged in counteracting the pernicious operations of the destructive myriads. To encourage and foster the increase of the innocuous classes of insects, should be the aim of every one connected with woodland management or plantations. This may, indeed, to a considerable extent, be achieved by preventing the too frequent and indiscriminate slaughter of many species of small birds and other forest denizens; for it is a remarkable fact, that the smaller birds feed much more generally (by a wise provision of Providence) upon such insects as happen to be injurious to tree life, than upon the harmless varieties. One of the most useful insects in attacking and destroying many of those allied species which are injurious to the Pine tribe, is the *Thanasius formicarius* (Linn.), and the destructive abilities of this small creature are truly marvellous, depositing its eggs not unfrequently in the wood-boring larvæ themselves, as well as in the bodies of many other descriptions of very destructive insects, and also in the larvæ of numerous kinds of destructive beetles which live between the bark and wood of decaying trees.

Remedies.

While it will thus be seen, from the foregoing cursory sketch of some of the numerous enemies of Conifera, that their name is truly "legion," it yet remains that some remedial measures should be pointed out to check the ravages of these incursive hosts, and so preserve the healthful amenity of our beautiful Coniferous favourites. The first suggestion that naturally falls to be offered, with the view of preventing, or at all events, of retarding, the attacks of predaceous insects, is the entire removal, after felling or thinning any plantation or strip, of all brushwood, refuse, or root-stumps, which may be left. Indeed, the instant transport of these outside the wood, and their immediate consumption on the spot, is the first safe-guard which can be suggested for healthy plantations. In the case of woods where insect attacks have become apparent on Silver Firs, Scotch Firs, or other common nurseries, the immediate felling and removal for burning of the infected victims may tend to stay or lessen the plague. Paring off the Grass all round infected trees, to the distance of a yard on each side, and burning the turf along with the diseased plant, is also a good and frequently an effectual remedy. Where it is practicable, and can be economically done, it is well, before planting any strip or ornamental belt of wood, to plough the ground deeply. This not only turns over the sod and affords less cover for insect life therein, but also affords a deep soft bed for the young roots of the new plantation, and thereby induces a rapid and healthy start, which is always beneficial to a newly-formed wood. Early thinning, boldly and fearlessly accomplished, so as to admit of a free circulation of air among the young plants, and to prevent overcrowding, and other obstructions to the radiation from the earth's surface, and evaporation from the trees themselves in their young state, has likewise a salutary effect in preventing the inroads of insect vermin. This is especially the case with Larch plantations, for Moss-covered bark, engendered by damp, close, and confined situations and habits of the tree, are fruitful of disease, and harbour innumerable parasitical foes

of the Pine tribe. When plantations have been once thinned, and are fairly established in growth, it suits very well to allow the second thinnings and prunings to lie in the wood for a year after being cut, and then to remove them suddenly in midsummer and burn them up. By this plan a vast number of those insects which prefer settling upon fresh cut and drying shoots and branches are destroyed; but as, generally speaking, in a first thinning of any wood, their presence would be rather in the way than otherwise, the plan suggested may be found effectual with a second or third thinning—say when the trees are sufficiently apart, and are probably from 12 to 18 feet high or thereby, so that a free circulation of air can play through them without being interrupted to any extent by the felled branches and other prunings during the first season after the thinning process has been effected. To prevent harbours for insects in hard-wooded plantations, the stools should be cut as low as possible, so as to prevent sprouting, and the formation of cluster heads and bush-like forms.—*Scottish Arboricultural Transactions*.

Indestructibility of Cork.—In taking down, a few years ago, in France, some portion of the ancient château of the Roque d'Ondres, it was found that the extremities of the Oak girders, lodged in the walls, were perfectly preserved, although these timbers were supposed to have been in their places for upwards of 600 years. The whole of the extremities buried in the walls were completely wrapped round with plates of cork. When demolishing an ancient Benedictine church at Bayonne, it was found that the whole of the Fir girders were entirely worm-eaten and rotten, with the exception, however, of the bearings, which, as in the case above mentioned, were also completely wrapped round with plates of cork. The fixings were completed by a layer of greasy-feeling clay, interposed between the cork and the masonry, and the parts of the walls opposite the ends of the timbers were of brick. It would be very difficult to believe that these extraordinary instances of the preservation of timber were not to be entirely attributed to the cork plates, the impermeability of which is well known. With experience saying so much in favour of a process so simple and inexpensive, it must be acknowledged that it deserves to be tried, more particularly for buildings of which we are more than usually anxious to preserve the timbers.—*Artisan*.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Autumnal Tints of the Aspen (*Populus tremula*).—I have been interested in Mr. McNab's able article on planting for landscape effects. I have wondered, however, that he only speaks of the Aspen Poplar in reference to its habit, and omits all mention of the glorious tints of gold and crimson with which it is now adorning the landscape here. Enclosed are specimens of the latter (and not the brightest) from a dish, now in our entrance hall, of twigs of Aspen stuck into green Moss.—E. P., *Braemar*. [The leaves sent—gold suffused with brilliant crimson—were extremely handsome.]

Poplar Leaf-stalk Distortions.—I have sent you some Poplar leaves with singular swellings on their stalks. What is their nature?—W. B., *Wood Green*. [They are produced by *Apilus lursaria*, which, at an earlier stage, makes curious swollen distorted bags or purses on them, which have now dried up into the form sent.—A. M.]

The Chokeberry (*Pyrus arbutifolia*).—Messrs. Osborn sends us from their rich collection of trees and shrubs at Fulham specimens of the branches of this, laden with leaves of a burning red hue. It is one of the most valuable of the many shrubs that assume brilliant hues in autumn, and like many of these it is a native of North America.

***Libocedrus decurrens*.**—This plant, which for so many years European botanists, following Carrière, insisted on calling *Thuja gigantea*—calling the real *Thuja gigantea* *Thuja Lobbi*, has been again named by Professor Koch. He insists that it is not a *Libocedrus*, and has made a new genus for it. He calls it *Heydenia decurrens*.

Raising Conifers from Seed.—Sow in spring in pans well drained, and filled to within half an inch of the rim with light sandy loam, placing the seeds evenly over the surface, and covering with fine soil. Place the pans in a cold frame. The soil should be kept moderately moist, and, when the plants appear, admit air freely, keeping them as cool as possible. In winter, protect them from frost by a covering of mats, and in spring prick off round the pots, putting about a dozen plants round the side of a 6-inch pot. Continue them in a cold frame for another year; then, after being well hardened-off, they may be planted out in lines 1 foot apart, allowing 6 inches between the plants in the lines. Water them in dry weather until they are again established. In two years they will be good plants, requiring to be again transplanted. Allow them double the distance they had before, or they may be planted out where they are to remain.

***Veronica lobelioides*.**—This is a shrubby variety of *Veronica* of the species type, with which I have been much pleased during the present season. It forms a dwarf compact shrub, about 18 inches high, with fine bright green foliage, and a profusion of spikes of bright blue flowers, which, as they become older, shade off into white. It is one of the most profuse flowering plants I know—every branch being clothed with the spikes, which proceed from the joints in opposite pairs, and which are produced in succession from every extending joint. From the tip shoots of the last year's growth laterals are emitted, from which the flower-spikes spring; and from the end of May or the beginning of June the plant continues to produce its pretty spikes till growth ceases in the autumn. It is one of the best of shrubs for the margins of shrubberies, and also for planting on rock-work.—*The Gardener*.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

The Flower Garden and Pleasure Grounds.

IN order to preserve the beauty of flower-beds and borders as long as possible, they should be frequently examined, and all decayed flowers and leaves at once removed. Look frequently over "carpet beds," as such plants as the Golden Feather Pyrethrum, *Stellaria graminea aurea*, and other hardy species may still be growing rapidly, and will consequently require to be occasionally stopped; this may, however, be discontinued in the case of such tender plants as the *Coleuses* and *Alternantheras*. The season is so far advanced, that a sudden and injurious depression of temperature may at any time take place, and it is, consequently, advisable to have at hand the means of covering up beds of tender plants which it may be desirable to preserve. Preparation should also be made for lifting and re-potting all plants that are to be kept for another year, whether intended for the production of cuttings in spring, or to be again bedded out in the flower garden. Old plants of most of the bedding *Pelargoniums* are generally found to flower more profusely than either autumn or spring-struck cuttings; and, such plants may, after being well cut in, be either potted singly in pots some 4 or 5 inches in diameter, according to the size of the plants, or, in order to economise space as much as possible, they may be planted tolerably close together in boxes or shallow pans; by adopting this method, a very considerable number of plants may be wintered in a comparatively small space. A similar system may also be pursued with plants of *Bouvardia*, *Lobelia*, *Lantana*, *Salvia*, &c.; also with *Coleus Verschaffelti* and its improved variety, together with the various species of *Alternanthera*; but, as regards the two last named families of decorative plants, it is necessary to place them at once in a moderately heated atmosphere, in order to get them established in their pots or pans as soon as possible. Single specimens of tender plants which may have, with the view of producing a desired effect, been planted or plunged in the flower garden, such as standard or pyramidal *Pelargoniums*, *Fuchsias*, *Dracænas*, *Abutilon Thompsoni*, &c., should now be pruned in where necessary, lifted, and carefully re-potted, and placed in their winter quarters; as should also *Auriculas* and other Alpine plants grown in pots, plunging the pots in cinder-ashes, or some other suitable material; but previous to doing this the drainage of each pot should be examined, and, if found defective, renewed. Cuttings of all sorts of bedding plants, which are fairly rooted, may still be freely exposed to the open air during the daytime, but should be covered up at night; while those which are only partially struck should have the advantage of a little artificial heat to enable them to complete the rooting process. The herbaceous border should still be gay with German *Asters*, and several species of late flowering *Phloxes*, *Solidagos*, *Tritoma Uvaria*, and *Aconitum japonicum*; the *Aconite* is an exceedingly valuable late-flowering plant, whose rich mazarine blue flowers bleed gracefully with the bright yellow blooms of the *Sternerbergia lutea*, autumn *Crocus*, and the *Colchicum autumnale*, and its white variety. On account of the frequent falls of rain which have been recently experienced, and the weather still continuing mild, Grass continues to grow rapidly, and lawns will still require to be frequently mown, while the fast-falling leaves of the Lime and of other early defoliating trees, together with worm-casts and other littery matter, render the daily use of the broom necessary in order to keep lawns and walks in proper order.—P. GRIEVE, *Culford, Bury St. Edmunds*.

Roses.

Where *Roses* are required to be in flower late in the autumn and at Christmas, select a few free-blooming Tea and Hybrid Perpetual *Roses* that are making late growth, and place them in a cold frame, over which some slight covering can be put, as sharp frosts may occur this month at any time, and the buds if touched, invariably turn black and die off instead of opening. Avoid also, using too much water over the plant; for, if the blooms become too damp, they rot off. Those requiring pot *Roses* for next year's forcing, should obtain them this month, so as to ensure good strong plants. See to such plants as were budded this summer, and loosen all ties where they require that attention, so as to prevent them from cutting the buds; also support strong growths, so as to protect the buds from being blown or broken off. Remove all dead flowers, so as to encourage lateral buds.—H. G.

Indoor Plant Department.

Azaleas that have set their flowers well, should have the young shoots neatly, but not too stiffly, tied up. Any *Heaths* showing signs of mildew should be dusted over with flowers of sulphur. Many of the

young central shoots should be removed, for if allowed to remain they are only a productive source of mildew, and that often unnoticed except upon close examination. *Heaths*, *Hedearomas*, *Dillwynias*, *Chorozemas*, &c., should now be housed, but though indoors, should have a free circulation of air. The *Pampas Grass* makes a good conservatory plant. For this purpose young plants of it should be kept in pots, plunged out of doors throughout the summer, and should be taken indoors about this season, just as they throw up their flower-spikes. *Coleuses* for keeping through the winter should be kept in small pots, and in airy houses, where they get well hardened, and consequently stand the winter better than they otherwise would do. In spring, after being re-potted and plunged in bottom-heat, they yield abundance of cuttings; some, however, strike cuttings now, to stand the winter, and to afford an additional supply in spring. Plants of *Solanum Capsicastrum* should be removed from the open air, where they have been plunged in beds, and either placed in frames or taken at once into the conservatory. Roots of *Lily of the Valley* should be lifted and potted for early forcing. Plants of *Mignonette* in 6-inch pots for winter flowering, should be thinned out a little if too thick. Some sow it in 4-inch pots, and after the plants attain a height of about 4 inches, the whole potful is shifted into a 6-inch pot without breaking the ball. *Liliums* that have done flowering should be laid on their sides out of doors, so as to prevent the soil from becoming saturated with water. *Clorodendron Kämpferi* should be dried off gradually in a cool house or out of doors. Those who care to have *Dielytra spectabilis* in bloom about the new year must soon bestow upon it some attention. About the latter end of the month a root or two of it may be dug up and potted into 32 or 24-sized pots, using leaf-mould and sandy loam in equal parts. If large specimens are required, a richer compost may be necessary when the plants receive their last shift; but a dozen or two of small plants, with plenty of bloom, are better than a huge specimen or two with a dense mass of foliage and a few spindly flower-spikes. After the potting and watering of the roots have been completed, they should be placed in a cool pit or frame, where they will speedily make fresh rootlets. When the pots become well filled with roots, the plants may be shifted to new pots a size or two sizes larger than those they now occupy. Where small plants only are required, they may be potted in the same sized pots again, adding a little fresh mould in the operation. When there is danger of much frost setting in, they should be moved to a *Vinery* or *Peach-house* that is likely to be started early in December, bringing the plants nearer the light and warmest part of the house as they advance in growth. Attention to sticking and tying out, and supplying the plants with weak liquid manure once or twice a week, when they are showing bloom, are all that is required to ensure the successful pot-culture of this highly ornamental and useful plant.

Violets.

The *Neapolitan Violet* is now beginning to open its buds, and the season has arrived when this gem among winter flowering plants should receive special attention. To ensure success and a continuous supply of flowers through the winter, a pit or frame facing the south should be filled with fermenting materials, consisting of leaves and stable manure well mixed together, the greater part being leaves which retain a steady bottom-heat longer than dung; the pit should be about 3 feet deep; if a dunghed, let it be 4 feet, so as to allow for sinking and settling down. The pit or bed having been prepared, cover the surface with 7 or 8 inches of soil, so as to leave the bed, when settled down, about 9 inches from the glass. Let the soil be two-thirds loam and one-third leaf-mould, and see that the loam is free from wire-worm and slugs, both great pests to *Violets*. Care must be taken in moving the plants not to shake the soil from the roots; pick off all side-shoots or runners and decayed foliage. Insert the plants in rows 9 inches apart and 6 inches asunder in the rows; give them a good watering, and shade during the daytime while the sun is hot; give plenty of air night and day, care being taken not to allow the bottom-heat to rise above 75°. As soon as they have commenced flowering and have made a little root-growth a little weak manure-water may be given, consisting of soot and sheep droppings mixed together in a tub; with this, water the *Violets* through a spouted pot so as not to wet the foliage. If red spider attacks the plants syringe in the morning and shade till the plants get dry; for too much moisture rots both flowers and foliage. During very sharp weather watch every opportunity to give a little air, as, in confinement, the flowers lose their odour; cover up early however, with a little sun-heat, if possible. When *Violets* are covered up mice and slugs often do much mischief; it is advisable, therefore, to look to the frame nearly every day, for if these pests are allowed to have their own way, not a single perfect flower will be left. By filling up a spent hotbed with some good plants of the *Czar*, put in in rows about a foot apart, and covered so as just to keep out frost, plenty of flowers will be produced, and when grown in this way they are much finer than

they otherwise would be, their flowers being erect and the mass of bloom greater.—H. G.

Indoor Fruit Department.

Selecting and storing soil for forming new *Vino* borders or for putting additions to old ones must not be neglected at this season. The best surface turf attainable should be taken to the depth of about 6 or 8 inches. The older, and fuller of fibres it is, the better. When cut into square pieces and laid grassy side downwards in mounds it is preserved in good order until required in the spring. When placed in narrow ridges the frost has a beneficial influence in melting such parts of it as may be of a clayey character. Here the most fertile soil for *Vine* growing is a substantial calcareous loam, obtained from the hill tops, where it is found here and there in small patches on whinstone. These patches, which have remained unmolested for ages, are rich in organic remains. As regards young *Vines*, such as were planted out during the past summer, if not already well ripened, they should be assisted to do so by means of a little fire heat. Thin away all lateral growths from them, in order that the air may play freely about the buds; keep a vigilant eye on *Grapes* hanging, in order to see that none are decaying; in cutting, take them from the top of the house first, say half-way down the rod; the bunches at the bottom of the *Vines* always keep better than those at the top; this is owing to the moisture rising and settling at the top of the house, while the bottom is comparatively dry; when well ripened it is surprising how perfectly *Grapes* will keep for months in the winter time if strict attention is paid to ventilation; see that abundance of air is given at the top of the house before sun-heat has induced moisture to rise; tardy ripening sorts of *Grapes*, such as *Muscat of Alexandria* and *Gros Colman*, may probably require a little fire-heat, in order to prevent the temperature from falling below 55°, and to ensure their perfect maturation. Scantily-rooted *Pine* suckers will yet require shading from bright sunshine; but, as such suckers are generally quartered in low pits and frames, the shading can, with little trouble, be removed when not needed. Keep the bottom-heat as near as possible to 85°, and see that the atmosphere is continually in a humid state. *Queens* intended for starting about the beginning of December should be kept very quiet; for these artificial heat, both for top and bottom, should not exceed 50°, and give no more water than what is absolutely necessary to prevent the plants from shrivelling. This early batch should consist of the most mature-looking plants, a condition generally indicated by the thick massive stem at the base of the leaves, and a centre somewhat open. Smaller plants, intended for succession, should be induced to grow for another month; water them as hitherto, and let the temperature range from 65° to 80°, according to the character of the weather outside. All damping overhead should be discontinued, except on very hot days; nothing is more hurtful to the *Pine* than water resting in the axils of the leaves; where it does so for any length of time the centre soon gets pale, tender, and blanched, and, not unfrequently, altogether decays.—J. Muir, *Clonsford*.

Hardy Fruit.

While dry weather continues it is good practice to get all manuring of fruit quarters, such as those devoted to Gooseberries, Currants, Raspberries, and Strawberries, completed; for the wheeling of manure among fruit bushes in wet weather is highly injurious, as when the texture of the soil gets destroyed in that way it can hardly be repaired. On open or clear ground the remedy for a ruined texture is deep digging or trenching; but, of course, that is impracticable among fruit trees or bushes. This is also a good season to top-dress any trees, on or off walls, that may have been overburdened by crops. A dressing of manure may yet invigorate the exhausted roots and help the buds to acquire greater plumpness. The roots, moreover, thus assisted will be able to replenish the exhausted tree at their leisure during winter. It is too often forgotten that the roots are never at rest unless frost-bound, and that the strength of the tree next season is much more a matter of winter replenishment than is generally supposed. Hence, doubtless, to a great extent, the success that attends autumnal top-dressings, which also preserve the roots unfrozen; and this immunity from frost confers a two-fold benefit on the tree. It protects the roots from the risk of mechanical rupture in the act of freezing, and enables them to carry on their slow, but sure, winter work without interruption. This is the month above all others for root-pruning rampant trees, sufficient vitality being yet left to heal the wounds, to prepare fresh roots—maybe to emit them; and there are several months before the plant, in which it can repair losses, and adapt itself somewhat to its changed condition before the top is called upon to grow, and the flowers to open. Continue to harvest fruit. The best mode of keeping *Golden Drop*, *Imperatrice*, and other *Plums*, is to hang them up by their stalks in front of a shelf, or

on a frame constructed somewhat on the principle of Kemp's useful *Grape* rail, dispensing, of course, with the tubes of water. A frame of such *Plums* would prove invaluable for dessert in October. As regards both Apples and Pears, there are various modes of storing them. Perhaps no better has been devised than laying of them on latticed shelves formed of Poplar or other flavourless wood. Deal is apt to flavor the fruit. Slate and iron are too cold, and all such linings as paper, cotton wool, &c., are better dispensed with. The fruit room should be cool, not damp, and kept as near to a uniform temperature as may be: 40 or 45° answer well for most fruit. The store room for fruit should be looked upon as a keeping, not a ripening, place. Practically, it is, to a great extent, both. But there are many Apples and Pears that have their flavour improved by being subjected to a higher temperature and a drier atmosphere for a week or so before use than the fruit room ought to furnish. It must also be borne in mind that few things more speedily lower the quality of fruit than a low temperature and an excess of moisture. Fruit should also be carefully sorted in storing. The best course is to divide it into three qualities—first, second, and third. In the last will be placed all fruit not likely to keep, and any too small for table and in anywise deformed. The first quality to be composed of the finest fruits, and especially those likely to keep the longest. This will save labour and trouble afterwards, as well as facilitate the safe and long keeping of the fruit, for nothing is so fertile a source of loss in this way as decay; one imperfect fruit has often been the seed-bed of destruction to an entire shelf, tray, or drawer of sound ones. In gathering, it need hardly be added that the ripest should be the first harvested, and that those unripe may, in most places, safely remain ungathered till towards the end of this month. Neither unripe nor over ripe fruit keep well, and the former is good for little or nothing after it is kept. The great art, and it is only acquired by much experience and not a few failures, is to gather each variety at the proper moment for keeping as well as for perfection of quality.—D. T. Fisher.

Trees and Shrubs.

This is a suitable time for inserting cuttings of evergreen and deciduous shrubs, such as *Laurels*, evergreen *Privets*, and striped-leaved *Yews*; also for collecting Acorns of different sorts, and seeds, as they ripen, of *Sycamore*, *Birch*, and other forest and ornamental trees and shrubs. Spread them out in an airy shed or loft to dry, when they may be stored away in bags or kept in heaps under cover until spring. *Birch* seeds may, with advantage, be mixed with sand slightly damp, and should be occasionally turned. The same may be done with the fruit or seeds of the *Arbutus* or *Strawberry* tree, the fruit of the various species of *Berberis*, common and Portugal *Laurels*, *Hollies*, *Privets*, and *Yews*—all of which should be sown in beds about the end of February or early in March. *Haws*, or the fruit of the common *Hawthorn* (*Crataegus oxyacantha*), should now be collected; and, after having been well mixed with sand, should be stored in clumps or pits for the next twelve months, and those thus treated about this time last year should now be sown in drills about 2 feet apart, and about 2, or not exceeding 3, inches deep, selecting for this purpose a piece of land which had been well manured during last winter or spring, and which had since borne a crop of some kind of vegetables, such as *Potatoes* or *Cabbages*, which would leave the land in excellent condition for this crop without further enriching. Transplant evergreen shrubs, &c., in the nursery, as soon after this time as possible, giving space for their further development by increasing the width between the lines as well as the distance from plant to plant. Trees and shrubs of all sorts while in the nursery should invariably be transplanted every autumn in order to induce, as much as possible, the formation of a compact ball of fibrous roots, and to this end all long or straggling roots should be cut back annually, so that the final transplantation may be effected with little risk of failure, and without giving an injurious check to the plants.—P. G.

Kitchen Garden.

If there is any doubt about the supply of Parsley being sufficient for the anticipated demand, there is yet time to transplant roots from the open ground into pots or boxes for use in January and February; and, even where there is an abundant supply well protected in the open air, it is always advisable to have some growing under glass for garnishing, as the leaves are usually fresher than can be obtained outside, especially during or after severe weather. It is generally after Christmas that this want is felt; therefore, there is yet time, if it is necessary, to add to the stock under cover. In the winter, when all space under glass has to be made the most of, a saving of room may be effected by growing Parsley as pyramids in 13-inch pots, as a very large amount of produce can be obtained from a limited space in this way. I have mentioned 13-inch pots because that is a handy size for moving, but larger or smaller pots would

do equally well, only very large pots would be rather heavy and clumsy to move about. Building up pyramids of Parsley is a very simple operation; first, take up a lot of strong Parsley roots, cut off all the large leaves, as it is the young growth that is wanted, and, in any case, the check in moving would cause most of the old leaves to drop. Then, having roughly drained the pots, fill them up level with good rich soil rammed well in to prevent settling. Ten stakes, about as thick as one's forefinger, will be required for each pot, and they must be inserted at equal distances firmly in the soil, close to the edge of the pot; five of the stakes should be cut to 2 feet above the pot, and the remaining five to 18 inches, leaving a short and a long one alternately. A small wire ring, 3 inches in diameter, will hold the sticks firmly together at the top, and a wire run round at the top of the short stakes, passing it round the end of each stake, and drawing it tight, will make a sufficiently strong framework for our purpose. Commence building up the pyramid by laying a row of plants horizontally at the top of the pot all round; the strength of the plants will furnish a guide as to the space each should occupy, but the strongest plants should be used in the bottom, reserving the smaller ones for filling in towards the top. Having thus placed the first row, fill in a layer of soil, pressing it down firmly; then another row of plants, and so on until the top is reached—when, to finish the pyramid off, finally place one large plant inside the wire ring at the top. For keeping up the soil, as the work proceeds, I prefer straw to hay-bands, as the latter, from their closer nature, encourages moisture to remain too much round the crowns of the plants. When all is completed, if there are any small cracks where the soil can run out, they should be rammed full of Moss. They may be supplied with water when necessary, and may remain in the open air for the present. An orchard-hen, or some place where frost is only just kept out, will be the best place for them during winter. Thin out all late Turnips and Spinach, the latter to 3 inches apart, and the former to 1 foot. All winter crops are now growing rapidly. Thinning and hoeing must, therefore, not be neglected; weeds, too, are feeling the effect of the present genial weather, and are coming up in quantities, and prompt attention must be paid to prevent them from seeding and causing trouble in the future. Proceed with earthing up Celery as required, banking up the successive crops well to throw off rains. Whenever there is any danger of frost occurring, see that Cauliflowers just coming in are sufficiently protected. The leaves tied closely over the flowers will probably be sufficient protection for the present, and it will also tend to keep them white and close. Veitch's Autumn Giant, in my opinion, is the very best Cauliflower grown, not only in the autumn, but for all seasons, except for forcing or very early work. British Queen and Ne Plus Ultra are the two best late Peas this year with us. We have gathered almost daily from these since the 1st of August, and shall continue doing so till frost cuts them off, as they are still full of flowers and young pods. The dwarf early kinds from the July sowings have also done well; but they lack the perpetual-bearing habit of the two sorts just mentioned, and the pods are small. Peas of the Ringleader or Dwarf Gem sections may be sown rather thickly in boxes; the young tops will be found useful for flavouring soups, &c., when Peas cannot any longer be gathered from the open ground. —E. HOBDAV.

Cottagers' Gardens.

The fine growing weather which we are now experiencing will have a marked effect on the growth of all kinds of green crops. Broccoli and Winter Greens will, therefore, make rapid progress, and will require frequent surface stirrings to keep down weeds, which are always difficult to eradicate in autumn. A full crop of Cabbage should be got out at once. Celery should be earthed up on a dry day, for, although a semi-aquatic plant, it is apt to decay at the heart if not thoroughly dry when earthed up. Advantage should also be taken of dry breezy weather for the ingathering and storing of crops of fruit and roots for winter use. Flower borders will also require frequent attention in the way of collecting decaying leaves and in maintaining neatness and order. Chrysanthemums and Dahlias should be effectually secured from wind by means of neat stout stakes. Window plants, as the season advances, should be kept somewhat drier than they hitherto have been, and a few hardy foliage plants should be introduced. Berry-bearing Aucubas are excellent window plants, as their leaves are so easily cleared from dust, and the bright glossy-leaved *Griselinia macrophylla* well deserves a place in cottagers' windows, as its foliage may be cleaned equally well, as that of the Aucuba and its colour is a more pleasing shade of green. *Ficus elastica*, and the feathery-leaved *Acacia lophantha*, are two of the best of all foliage plants for windows during the winter months. A few bulbs, to bloom in spring, should now be potted and plunged under ashes in order to get their roots in advance of the tops, without which they seldom give satisfaction. —J. G.

THE LAMBTON CASTLE GRAPES.

WHEN, last November, we gave an engraving and a few particulars of the largest bunches of Black Hamburgs that had been recorded up to that date, we had not the most distant idea that a bunch, well nigh double the weight of it, would be produced by the same Vine this year. Such, however, is the astonishing fact; for, as many of our readers are already aware, Mr. Hunter, gardener at Lambton Castle, produced and exhibited, at the Belfast International Show last August, a bunch of Black Hamburg Grapes weighing 21 pounds 12 ounces—not 20 pounds 12 ounces, as reported in the GARDEN. We think we must be correct in saying that this is the most extraordinary production in the way of fruit that has been recorded in the annals of horticulture, outdistancing very far those large bunches of the large and coarse-growing Syrian Grape grown by Speechly, Dickson, Fowler, and others, the heaviest of which weighed a trifle over 20 pounds. Among other most remarkable products may be classed two or three Providence Pine Apples grown at Gunnersbury Park, by Mr. Mills, which weighed 15 pounds each—a feat in Pine growing which may now be considered eclipsed by the 8 pound Queens and 11 pound Smooth Cayenne Pines grown by the late Mr. Ingram (Frogmore) and Mr. Sandford (gardener to the Earl of Bective), whose Queen at Manchester last year was 8 pounds 4 ounces—more remarkable, to our mind, than a 15 pound Providence, especially when each plant had the whole of one light of a pit and a cartload of soil to grow in. The Lambton Castle bunch of Raisin de Calabrie—not Foster's White Seedling, as reported in the *Gardeners' Chronicle*, weighing 15 pounds, was also a very remarkable production, quite on a par with a 20 pound Syrian. It will, no doubt, be supposed that these bunches, and especially the Black Hamburg, were the only bunches produced by the Vines which bore them; a note of the facts connected with these Vines is therefore quite worthy of a place in garden literature. The Vine which bore the Black Hamburg bunch was struck from an eye in 1869. It was cropped the second year after planting it, and bore six bunches, one of which Mr. Hunter staged in his first prize collection of eight bunches in 1872. In 1873 it bore eight bunches, one of which, weighing 13 pounds 4 ounces, was the heaviest of any black Grape shown at the Manchester International in 1873; the smallest of the other seven bunches weighed 4 pounds. This year, besides the monster bunch in question, the same Vine bore five bunches; and within 2 feet of the great bunch hung one of most beautiful symmetry, weighing 11 pounds 2 ounces—the remaining four bunches weighing 13 pounds 13 ounces. We had the pleasure of inspecting this remarkable Vine a few days before the Belfast show, and considered the 11 pounds bunch the most lovely bunch of Black Hamburg we had ever seen. It was on a par with the Glamis Castle Black Hamburg as regards quality. Here we have a Vine bearing six bunches, of the aggregate weight of within a few ounces of 47 pounds—nearly 25 pounds weight of Grapes, besides the one bunch that turned the scales at a stone and a half!! If this is an accident—as the *Gardeners' Chronicle* has it—it is one which it does not require a lens to see! These are not the only remarkable Grapes we inspected in the same house. The Vine that bore the Raisin de Calabrie had other five bunches scarcely less than the 15 pounder; and there were very large Muscats; immense Trebbiana, from 10 to 12 pounds, we should say—after guessing within nearly a pound of the two celebrities; Foster's Seedling, of immense size and splendid quality; and Gros Guillaume, certainly not less than 14 to 16 pounds,—and these facts increase the astonishing nature of the accident! If these productions are accident, then so were the 15 pounds Providence Pines, the 8 pound 4 ounce Queens, &c. It would be easy to indulge in many reflections regarding these monster bunches—not referring to the giant one at all. We might not be so facetious as a gardener who pulled Mr. Hunter aside at Belfast, and asked, "How many Vines he had buckled on to the production of that bunch;" or conceit, for a moment, the idea of its being the production of many bunches grafted together when young. All such speculations and reflections are entirely unprofitable. A more practical question lies in asking if there is anything remarkable in such herculean work on the part of a whole house of Vines. As to soil, it is the same sort that had been used for Vines for years before these Vines were planted. The soil is a strong holding soil; the Vines are grown at somewhat between 3 and 4 feet apart, up a long rafter of a 22 feet wide lean-to Vinery. The Vines are allowed to carry a very full complement of lateral growth and foliage, are very copiously watered and fed, and are remarkably strong and thick in the hole for their age. It is useless to suppose that as these Vines get older they will continue to bear such large bunches; but, fine as they are in berry now, we predict, if nothing happen to them, that they will improve in size of berry if they decrease in size of bunch—and that can hardly be said to be progress in a wrong direction. A strong holding soil, well drained, is the soil for sustaining Vines in a condition to bear really good Grapes over a long series of years. We

remember being out on a tour of gardens some years ago, and of seeing Vines growing in many Vineries, over more than a dozen shires, and invariably found the finest Vines and Grapes where they were growing in strong holding soil, well drained. On light gravelly or sandy soils they will do wonders while the fibre of the turf of the border is decomposing; but when that goes, the Vines go too, and nothing but fresh supplies can keep them in stamina. On the other hand, in heavier loams, when the fibre is gone, they do not so much miss it, and with rich top-dressing they go on for generations, it may be, bearing fine Grapes. We would instance one case, and that is the Black Hamburgh and Muscat Vines at Wishaw House—growing apparently in clay, well-drained, bearing splendid quality of Grapes for, we should think, well nigh forty years now—during which time many Vines in light soils have been a mere flash in the pan, to be grubbed out in due time. Instead of over-draining in such light soils, or of aerating underneath, it would be much better for the Vines to keep all air from the border, except that which finds its way by ordinary pressure, and to mix some clay with the soil, if such could be had. Time is a wonderful revealer of secrets in Vine-growing, as in everything else. Since writing the foregoing, we are enabled to quote from the *Gardeners' Chronicle* the following charitable (?) solution of the mystery of giant productions:—

GIANT BUNCHES OF GRAPES.—I was told the other day by a first-class gardener that these huge and ungainly monstrosities could be produced by the grafting of bunches on to the stem or shoulder of the one to be the future giant. Is this so? and, if so, will it not account for the appearance of these remarkable, but scarcely useful, productions?—POMONA.
We have recently heard the same thing, and intend to have the experiment tried another year.—Eps. *Gardeners' Chronicle*.

Any such unworthy suspicions against the Speechlys, Fowlers, Dicksons, and Hunters, of large Grape notoriety, we consider to be utterly unworthy the countenance of our contemporary, who owes vastly more to practical gardeners than they owe to it. That any one should, to say nothing worse of it, be silly enough to raise such suspicions against these exhibitors is, to our mind, most reprehensible. Does "Pomona" and our contemporary suppose that men such as Mr. Fowler, Mr. Dickson, and Mr. Hunter, surrounded by a number of assistants—who are cognisant of their masters' every movement in the garden—would run the risk of being detected in such deceptive trickery, supposing them capable of it? This, we admit, is taking the lowest view of the integrity of such men, who will never be suspected of any such deceptions by those who know them thoroughly; and the *Gardeners' Chronicle* should never have allowed any such suspicions to have soiled its pages. Disgraceful things have been said of gardeners on many occasions, since the time that Mr. Mills grew the monster Pine Apples until now; and we, for one, protest against such conduct towards a class which, we hesitate not to say, numbers in its ranks as large a proportion of men who would not be guilty of such an immoral manner of winning a prize as are to be found in any other. No gardener will say, nor do their growers pretend, that these monster bunches are so useful as they are rare and wonderful; but prizes are offered for them at International Shows, and those who countenance the offering of such prizes should behave more charitably towards the winners of them, and not class them, by suspicion, among the base and dishonest.—*The Gardener*.

FLOWERS USED AT FUNERALS.

SIR RICHARD STEELE, in his play of the "Funeral," makes the undertaker, *Soble*, thus upbraid his servant, who it appears usually acted as a mute—"Look, yonder, that hale, well-looking puppy! You ungrateful scoundrel; did I not pity you, take you out of a great man's service, and show you the pleasure of receiving wages? Did I not give you ten, then to fifteen, now, twenty shillings a-week, to be sorrowful? And the more I give you, I think the gladder you are!" What a satire on our wretched customs! for it is hardly possible to conceive anything more unbecoming, tasteless, and unpleasant, than our present way of burying our dead. How often are the scanty resources of a bereaved family, taxed to the uttermost to pay for what is not only most unnecessary, but repulsive, to all persons of true feeling? But I would fain hope that we are losing our taste for mutes, hearses, feathers, palls, and the rest of the ghastly paraphernalia with which it has been our wont to flout the calm majesty of death. Would that we could at once, and for ever, cast them aside, and try to render our funerals graceful and becoming. This is not impossible; Nature is a great consoler; let us consult her, and, above all, use as decorations her lavish gifts of flowers. I have often observed how wisely they are employed in this way in Germany. Not many years ago, I joined the long procession of relatives and friends who followed a celebrated physician, to his last resting-place in a lovely cemetery near Heidelberg. There was little outward

sign of mourning, but the coffin, conveyed in an open car, was literally covered with wreaths of white flowers—Christmas Roses and Snowdrops for the most part, as it was in December.

The other day I witnessed the funeral of an old friend in one of our northern counties. The coffin, covered by no hideous pall, was adorned by three chaplets, one pure white (*Stephanotis*), one, of which the foundation was sprigs of Bay, was made of crimson Roses, the other white and yellow Roses with Lilies, also entwined with Bay; the cross at the head was of crimson Roses. I had an opportunity of carefully examining the wreaths, they were composed of strong wire which was first covered with dark green braid or ribbon, the flowers and branches of Bay were woven in together, the flowers being first carefully wired; the effect was most lovely. The practice of this kind of floral decoration is now becoming general; I wish it were universal. I will now mention the flowers which appear to be specially adapted for funeral wreaths. In early spring we might have Laurustinus, Primroses, Violets, white Narcissus, white and red Hawthorn. Then for "odorons chaplets of sweet summer buds," Roses of all colours; white and yellow Dahlias (when not too large) look very well. All varieties of white Clematis and white and yellow Jessamine, also *Stephanotis*, white Geraniums, and Carnations. Later on in the season, when most flowers are over and autumn's rough winds "shatter their leaves before the mellowing year," *Chrysanthemums* of all colours may be used. Christmas Roses and Holly carry us on to spring again. The Bay is almost the only suitable foliage for funeral wreaths, with the exception of the leaves of the different flowers which should be interwoven with them; it will last fresh for days if merely sprinkled with water.

I am not now writing about flowers for graves, but merely advocating the more general use of them at funerals, as one step towards an entire change in our present customs on those occasions. Time would fail me to do more than glance at the fine things which our poets and old writers have said on this subject: "Sweets to the sweet," exclaimed the Queen of Denmark, as she cast flowers on the untimely dead. "Let me be used with honour, strew me o'er with maiden flowers, that all the world may know I was a chaste wife to my grave," said the ill-fated Spanish Katharine. Spenser bewails the death of "Astrophel" (Sir Philip Sidney) in several very "doleful layes unto the time address, as fittest flowers to deck his mournful hearse."—Alluding to the well-known custom in those days of fastening valdeictory poems to the hearse. He further exhorts the dainty "shepherd lasses" of Elizabeth's Arcadian court:—

Instead of Girland wear sad Cypress now,
And bitter Elder brokeu from the bough.

Sir Thomas Overbury's "Fair and happy milkmaid's" best wish is, "that she may die in the spring-time, and have store of flowers stuck upon her winding-sheet." I cannot conclude better than by quoting the well-known words of our great Puritan poet, who thus writes of the floral honours due to his *Lycidas*:—

And call the vales and bid them hither cast
Their bells and flourrets of a thousand hues,
Throw hither all your quaint enameled eyes,
That on the green turf suck the honied showers,
And purple all the ground with vernal flowers,
Bring the rathe Primrose that forsaken dies,
The tufted Crow-toe and pale Jessamine,
The White Pink and the Pansy freak with jet,
The glowing Violet,
The Musk Rose and the well-attired Woodbine,
With Cowslips wan, that hang the pensive head,
And every flower that sad embroidery wears;
Bid Amaranthus all his beauty shed,
And Daffadillies fill their cups with tears,
To deck the laureate herse where Lycid lies.

—W. N.

How Errors are Disseminated.—"The American Aloe," says a writer in the *Christian Weekly*, "is one hundred years in getting ready to bloom," &c., all of which, to use a vulgar phrase, is "bosh;" but somebody started the story on its travels centuries ago, and those who possess the faculty of writing prettily about things of which they are profoundly ignorant have kept it a-going. Probably our correspondent of the *Christian Weekly* obtained his information from some other equally unreliable source, and thousands of children will read his story, and repeat it in after years, believing it to be true, and thus errors are disseminated.

OBITUARY.

We have to announce the death of Mr. Masters, of Canterbury, which took place on the 26th ult., at the ripe old age of seventy-eight. As a nurseryman he was long and well known, and the valuable collection which he formed in the Canterbury nursery is illustrated by a reference to the "*Hortus Cantuariensis*," which he published.

THE GARDEN.

"This is an art

Which does mend nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

THE BEST CONIFERS FOR BRITAIN.

THE Larch is, I am afraid, doomed. The disease goes on extending its ravages and increasing in malignity; at first, it did not show itself in young trees, which, until they had reached the age of twenty, or even thirty, years, were spared; but this immunity is no longer extended to them. Now even newly-planted trees, trees still in the nursery, are attacked by it, and I lately observed plantations of four or five years old dying off wholesale. The present year, indeed, seems to have been peculiarly favourable to the development of the Larch disease, and I may note, in passing, that it has been an unusually dry one. Various circumstances, indeed, seem to indicate that drought has much to do with the disease. Both the Spruce Fir and the Larch, as well as *Pinus excelsa*, all of which suffer from disease, come from more rainy countries than ours, and it is possible that owing to the system of excessive drainage which has, during the last sixty years, been carried to such an extent in this country (and more especially in Scotland, the focus of the disease), our climate has undergone such a change that these trees are unable to thrive in it. There are, I think, facts and considerations which support this view, and if that be so, there seems every prospect that we shall lose both the Larch and the Spruce Fir, and any other tree for whose constitution drainage has rendered our climate unfit. Even, however, should the worst come to the worst, it is more than probable that there will always be a certain demand for both Spruce Fir and Larch for cultivation in exceptionally favourable (rainy) situations. That rainy situations are better suited to these trees than others is tolerably clear; for it was in the eastern and drier parts of Scotland that the disease first appeared; it was only gradually that it proceeded to the more humid west; and even now we are told that it is scarcely known in rainy Ireland. If the Larch and Spruce Fir both fail us, what are we to put in their places? This must be answered alternatively. If we suppose that the disease which is killing them proceeds in any respect from unsuitable climate, we must proceed to fill up their places in a different way from what we might do if we had not to take the climate into consideration. If the climate is the cause, we must avoid that of the suffering trees, and look out for the denizen of a climate more like our own. If the climate is not the cause, then there can be no objection to taking a substitute, say for the Larch, from a climate similar to that of the native country of that tree. All that we have to do is to pick out the nearest approach to it in grace, beauty, and other properties. In such a case, for the Larch, we should prefer the Deodar. We might, indeed, take the Siberian or North American Larch (*Larix sibirica* or *L. pendula*), which we have not seen attacked by the disease, but our experience on that point is not worth much, for these Larches have not been planted out in Britain in sufficient quantities to allow anyone to generalise respecting them; and even, although they should prove disease-proof, they have neither the beauty nor the elegance of their European relative. The Deodar has both, and much of its peculiar style, and, although its timber is not equal to that of the Larch, it has special excellencies of its own. We have now abundant materials by which to judge of its merits, whether as a single tree, or in avenues, or in masses, and in all it compels our homage; but we do not think anyone can fully appreciate its beauty who has not seen it grown in masses. This may be seen in the New Forest, in the south, and at Riccarton, near Edinburgh, in the north, besides, no doubt, many other places that do not occur to us at the moment. But, suppose that, in course of time, the Deodar should fail too, what tree should we then select in its place? The experience which we have been accumulating during the last fifty years enables us to answer without hesitation, the Douglas Fir—which, with a good deal of the density of foliage of the

Spruce, combines much of the grace and elegance of the Larch—and has a timber as valuable as that of either; besides special beauties, and other valuable properties peculiar to itself. Its range extends from Mexico to Vancouver's Island, and from the Pacific to the Rocky Mountains. It grows, at one place, in a climate as moist as that of the Himalayas, and, in another, almost as dry as that of Egypt—here in a tropical heat, there among Arctic snows. Its habit and its timber vary according to locality, and it seems to thrive in all, although not equally luxuriantly or to reach the same dimensions in all. In British Columbia it reaches 300 feet in height, while in the Rocky Mountains and in Mexico it does not exceed 90 feet in height. In British Columbia, its timber is springy and elastic. In the Rocky Mountains it is hard, resiny, and liable to warp—all indicating the possession of the power of adaptation and accommodation to circumstances, with the capacity of modifying its character to suit them. It has shown this power in Britain already. No sooner grown here than it has thrown off the straight and stiff erectness which characterises it in its native forests. Instead of continuing here, as it might naturally have been expected to do, *roide comme une Anglaise*, as our neighbours accuse our ladies of being, it has thrown out its arms and taken an attitude as free as that of a Hercules. It is, in short, a tree formed by Nature for meeting such a difficulty as the failure of the Larch presents, and standing, as it does (so far as appearance goes), mid-way between the Larch and Spruce—it may well be taken as a substitute for both. Next to this Fir, whether as a substitute for the Larch and Spruce, or as independent trees worthy of cultivation in the future, we place in the first rank the Hemlock Spruces, including under that name the Hemlock of the Eastern States of America and those of the Western, viz., *Abies Albertiana*, *A. Hookeriana*, and *A. Pattoniana*, of which last we spoke lately; also *A. Tsuga*, for large scrub-work; the others for trees. Among the Spruces *Abies Menziesii*, *A. Picehta*, and, if we could rely upon it, *A. Morinda*, but we fear, although it has been doing very well since 1860, a similar winter may prove too much for it in many places. Of Silvers we prefer (besides our European, *Picea pectinata*), *P. nobilis*, *P. magnifica*, *P. amabilis*, and *P. grandis*, under which head we include *P. Lowiana* and *P. lasiocarpa* as synonyms, on the strength of the variation in leaf and habit which we have seen in *grandis* in its native habitats. *P. cephalonica* seems to do better than *P. pinsapo*; but we can spare neither, and we have been surprised to see how well *cephalonica* does in cold districts and high elevations. *P. Webbiana* and *P. Pindrow* (whether they be distinct species or varieties of each other, as we believe them only to be), are so beautiful and so magnificent that, even although we should lose them every few years, we would keep on planting them again and again. Of Firs, the staple, after the Scotch Fir, is *P. austriaca*, the merits of which is now generally known, and *P. Pinaster*, for sandy places; *P. contorta*, from California, is also a fine tree. Of the Cembras, the most promising, after the European species, is the new one from Japan, introduced some few years ago by Mr. J. G. Veitch, and called *P. Koraiensis*; it appears to be the same as *P. parviflora*, although the figures of the cones, published by Siebold, look very distinct, but the one is figured open and the other shut, which may be the explanation of this; but we have lately seen *Koraiensis* in cone in the nursery of Messrs. Turnbull, at Perth, and the cone which that plant bears is identical with Siebold's figure of *parviflora*. Its leaf has a beautiful white silvery side, which gives it almost a variegated appearance, and as it seems hardy it will come in well with any of the dark Firs, such as the European Cembra or *austriaca*, or the Scotch Fir. We might pass over the Pines having leaves three in a sheath, without notice, were it not for *Pinus ponderosa*, which was the tree which struck us more than any other in California. The trunk becomes an immense solid Ionian pillar, almost as big at the top, 100 feet up, as at the bottom, and its diameter is often from 6 to 8 feet; lying on the ground it is an insuperable obstacle—nothing can get over it, and it is often felled in California in a continuous row, one after another, to serve as a fence. This has already been recognised as synonymous with *P. Benthamiana*, *P. Craigana*, *P. Beardsleyi*, *P. Sinclairiana*, &c., but we must also add *P. Jeffreyi* as a synonym. *P. ponderosa* and *P. Jeffreyi*

grow in adjoining districts, and the one passes into the other, that is, is intermixed with it, and the only difference that we could see was the size of the cone, and that the bark of *P. Jeffreyi* had a redder hue than the variety with the smaller cone. It grows very well in this country in the south of England, and it is most desirable that it should grow well everywhere. None of the pseudo-Strobi seem adapted for this country. We are rather disappointed with the progress of the different species introduced a few years ago from Japan. The most remarkable, the Umbrella Pine (*Sciadopitys verticillata*), is excessively slow in growth. We have scarcely left ourselves space to touch on the Cypresses; we shall only say of those introduced within the last few years that *Cupressus Lawsoniana* comes first in our estimation; *Thuja gigantea* (Lobbii), second, and *Libocedrus decurrens* and *Thujopsis borealis*, third. We should have placed *Wellingtonia gigantea* and the red-wood *Sequoia sempervirens* higher, but we have doubts whether they will ever do thoroughly well with us. This is a point still *sub judice*, and there is sufficient encouragement to warrant everyone in trying them, but not in trusting absolutely to them. In some parts of the kingdom the Monterey Cypress (*Cupressus Lambertiana* and *macrocarpa*) has continued to do well, notwithstanding the slaughter of it that took place in 1860 and 1866, in what might have been supposed to be the mildest regions. It possesses such beauty, and grows so rapidly, that we would put it in the front rank if we could only depend upon it.

A. M.

TWO HUNTINGDONSHIRE GARDENS.

Hinchbrook.

This noble and spacious mansion, so rich in historical associations, is supposed to have been built by one of the ancestors of Oliver Cromwell on the site of an ancient nunnery, in the reign of Henry VIII. James I. when on his journey from Scotland to London, to take possession of the crown, made Hinchbrook one of his resting places, and was so lavishly entertained by Sir Oliver Cromwell (uncle and godfather of the "Protector"), that the king is reported to have said at parting "Merry mon, thou hast treated me better than any one syn I left Edinbro." It remained in possession of the Cromwell family till 1627, when it was purchased by Sir Sidney Montague, the father of the first Earl of Sandwich, a noble family, in whose possession it still continues. The date 1602 is on the south front of the mansion, but the northern part of the building appears much more ancient, and is richly adorned with beautifully executed ornamental work. The grounds on the southern and western fronts are somewhat extensive, and well varied; but the chief glories of Hinchbrook are its grand old trees. Standing in the pathway, south of the mansion, and looking westward, across the wide expanse of smooth closely-shaven green turf, the eye takes in at a glance one of the prettiest tree pictures it is possible to imagine. In the foreground are several grand old Cedars of Lebanon, with their lower branches sweeping the turf; a little in the rear of these, but towering above them, is a fine purple Beech; whilst the background is filled in with monster Elms, Limes, and Oaks—grand old remnants of the past, associating fitly with a mansion that dates back for centuries. A small flower garden, of simple but tasteful design, is cut out on the Grass in front of the drawing-room, and this is kept gay in summer with the usual kinds of bedding plants; and, when the beds are cleared in autumn, they are planted with bulbs and other spring-flowering plants. Ascending a flight of stone steps, a terrace walk is reached, supported by an Ivy-clad parapet wall, from which magnificent views are obtained of the river Ouse, meandering like a silver thread through the broad green valley; and, away beyond, the view extends for miles over gently rising ground, forming as pretty a picture of English pastoral scenery as could anywhere be met with. About the centre of the terrace is an ancient sun-dial, said to have been set by the celebrated navigator, Captain Cook. Descending from the terrace, and passing round the western side of the mansion, a delightful peep is obtained through a vista in the shrubberies away through the dressed ground to a walk called the Walnut-tree Walk, in the distance. The conservatory, an ornamental structure with ridge and furrow roof, stands back from the mansion, on a platform or terrace, with a flower garden in front of somewhat intricate design on gravel. A broad central path intersects the garden in the centre, dividing it into two equal portions; and another path runs round the outside. There is also a broad verge of turf on each side of this path, with standard Roses planted at short intervals, and the whole is bounded by climbing Roses, trained to iron supports, and festooned between the uprights. The conservatory is in three divisions; the eastern

one is filled with Ferns, amongst which we remarked several plants of the Bird's-nest Fern, and good representatives of the genera *Adiantum*, *Pteris*, *Blechnum*, &c. In the central division is a fine India-rubber plant, the head of which is about 12 feet in diameter. The western division is filled with a mixed collection of flowering plants. After passing one or two isolated flower gardens, a fine old Beech, standing on the open lawn, and measuring upwards of 20 feet in circumference at 1 foot from the ground, arrests attention. It appears to have met with some injury in its youth, for, about 5 feet from the ground, it has branched into four leaders, each as large as a good-sized tree, and which rise almost perpendicularly, making its top, as one glances upwards, like a thicket of branches. Here are also several fine old Scotch Firs, and one or two handsome young trees of *Wellingtonia gigantea*, which appear to thrive well in the neighbourhood of Hinchbrook. Altogether, the grounds at Hinchbrook are very tastefully laid out. There is a good breadth of turf near the mansion, free from that senseless dotting about of trees or flower-beds which too often disfigure even good gardens. The kitchen garden contains about 1 acre within the walls, and is well stocked with fruit trees and vegetables. On the lower side of the garden is a range of lean-to houses devoted to Grapes, Peaches, &c. There is also a span-roofed stove. The park, which is of moderate extent, contains some noble old Elms and Limes.

Cromwell House.

This, the birthplace of Oliver Cromwell, will always possess interest of no ordinary kind to the student of history. It has, probably, however, been partly, if not altogether, rebuilt since it was sold by the Cromwell family in 1631. It is now a square Grecian structure, overlooking small but pretty grounds, in the midst of which stand the remains of an old wall thickly covered with Ivy, probably all that is left of some grand old building. The charm of this place consists in its historical associations, and in the quaint pleasing way in which the grounds are laid out; although the modern system of ribbon borders and bedding-out is introduced and well managed, there are also here and there delightful little bits of picturesque planting with such materials as Yuccas, and other hardy plants; and, near the boundary path, are retired shady nooks planted with choice collections of hardy Ferns. Roses, Rhododendrons, and shrubs of all kinds appear to thrive well here. The glass erections are not numerous, but Grapes and greenhouse plants are well grown. There is a walk leading through the kitchen garden with a border on each side, in which are planted standard Roses, Peonies, and many old-fashioned hardy plants which are interesting at all seasons.

E. HOBDAV.

Public Park for Reigate.—Lord Somers has just presented to Reigate, in the shape of a lease to the Mayor and Corporation for 999 years, at a nominal rent, several acres of land, immediately adjoining and overlooking the main street, as a pleasure and recreation ground for the inhabitants. Formerly the place was a sort of wilderness, a receptacle for all kinds of rubbish. To rid the town of what was regarded as a public nuisance, Mr. Wilson Sanders and a few others having obtained the necessary legal sanction from Lord Somers, converted the place into a delightful pleasure ground, with pretty walks and many flower-beds and seats beneath the shade of ancient Elms. In this transformed condition it has now been handed over to the Corporation, to be maintained and kept in order out of the municipal rates. The Castle Grounds, for such they are called, possess special interest as being the site of the ancient fortified Castle of Reigate, said by Aubrey to have been built anterior to the Conquest, and supposed to have been chosen by the Romans to guard the old line of communication to Croydon. The structure has now completely vanished, its demolition having been nearly accomplished during the Civil Wars, and the only relic of it is a barbican, built out of the ruins about one hundred years ago. The Castle court now forms the higher and principal part of the pleasure ground, and from it is to be seen one of the most picturesque landscapes in Surrey. There is an uninterrupted view down the valley to Dorking, with the grand chain of hills on the north side; and, looking southward, the houses and streets below, backed by the high straight ridge of Lord Somers' park beyond, present an unusual appearance. Under the pleasure grounds run some extensive caves, hollowed out of the solid sand-rock with remarkable accuracy, and supposed to have been contemporaneous with the castle. The principal cave is called the Baron's Cave, the tradition being that the confederate nobles here first debated upon and arranged the terms of Magna Charta. A massive flight of stone steps, supposed to have led up from the caves into the castle, still remains, and a part of the old moat is now included in the new pleasure ground. The estimated cost of keeping the place in order is less than £200 a year.

NEW ERYNGIUMS.

PROBABLY no genus of plants among Dicotyledons presents among its species more diversity of form than the Eryngiums, a genus which has almost as many representatives in the Old World as in the New. Among the foliage alone, indeed, there is great dissimilarity, some varieties having perfectly entire and smooth leaves, others lacinated and waved ones, and between these there are all sorts of intermediate forms: the most extraordinary form, however, is that which is peculiar to a group of species belonging exclusively to America, and particularly to Brazil, the Argentine Republic, and Mexico. These are characterised by simple linear leaves, elongated, and with parallel veins, such as are ordinarily found only in Monocotyledons. It is to some of these latter that we now propose to direct attention. The genus Eryngium is represented in our gardens by a number of European and Oriental species, all remarkable for their blue or amethyst tint, a colour which extends to the divisions of the involucre, and even to the flowers themselves. Among them, one of the most singular is *E. alpinum*, from the elevated meadows of the Jura, of Provence, and of the Dauphinian Alps, but it is a plant rarely found in cultivation, where under this name one more often meets with *E. planum*, of the mountains of Austria, a hardy

*Eryngium Lasseauxii.*

species widely diffused in botanic gardens. It is, besides, rather ornamental, and though less elegant than *E. alpinum*, would, nevertheless, be a good addition to our gardens. The two Eryngiums, however, which are most frequently met with in cultivation are, *E. amethystinum*, from the dry districts of Croatia and Dalmatia, and *E. ceruleum*, which grows in Asia Minor on the Caucasus and Lebanon. Both these have blue flowers, and the same colour also invests the involucre and the upper extremities of the stalks. Another very pretty species also, is *E. Oliverianum*, which is sometimes in cultivation under the name of *E. alpinum*. The Sea Holly (*E. maritimum*), from the shores of the Atlantic and Mediterranean, forms a fine contrast with surrounding plants; and, lastly, there is *E. giganteum*, a tall species from the mountainous regions of Armenia and of Iberia, which deserves to be more extensively known than it is. Some dozen years ago, these were the only species of Eryngiums which we had; all of them have leaves more or less entire or divided, and in this respect are different from those to which we are now about to direct attention, and which have linear leaves traversed by parallel veins, somewhat resembling Bromeliads. Of this class are the three following, viz., *E. aquaticum* (*E. Yuccafolium*), from Pennsylvania and Virginia; *E. paniculatum*, originally from Brazil, and frequently cultivated under the name of *E. Bromeliæfolium*; and

lastly, the true *E. Bromeliæfolium*, from the humid forests of Mexico. But of all the long narrow-leaved kinds, none equals some raised from seeds sent to Paris some years ago by M. Lasseaux. These seeds, which were sown immediately, soon germinated, and the young plants obtained from them soon developed their true character. Three years afterwards many of them flowered, and were successively described by M. DeCaisne, who recognised, besides *E. pandanifolium* and *ebRACTEATUM*, three new species, viz., *E. Lasseauxii*, *eburneum*, and *platyphyllum*. *E. Lasseauxii* differs from *E. pandanifolium*, which it much resembles in foliage, inasmuch as it is more upright and glaucous underneath, but, above all, by its flowers being whitish, instead of being of a reddish, violet. The most remarkable kinds are *E. Lasseauxii*, *pandanifolium*, and *eburneum*; *E. platyphyllum*, characterised by its large leaves, spread in a rosette upon the soil, might yet, if its foliage were more abundant, be classed among the preceding. As to *E. ebRACTEATUM*, whose inflorescence resembles that of some *Sanguisorbas*, if it cannot, on account of the smallness of its straight leaves and the sharpness of its stem, be added to them, it yet carries a certain amount of interest with it on account of its singularity.

These plants are not hardy in the climate of Paris, and are only able to withstand the winter when protected. In the south of France Eryngiums acquire large dimensions. In the west, too, they are decidedly hardy, and in the botanic gardens at Brest, there was formerly a specimen of *E. pandanifolium* the stems of which, when in bloom, were at least 16 feet in height. They are easily increased either by means of seeds or by the splitting up of adult specimens. In the first case, the seeds, which are produced in abundance about Paris, are sown as soon as gathered in pots or in pans, which are placed in frames. In the second case the operation is performed either in spring or summer; each shoot, if rooted, is placed separately in a pot, and either set out-of-doors or placed in a cold frame. When large enough they are planted on the lawn, either separately or in masses, and in either case produce a grand effect.—*Revue Horticole*. [We were very much struck with the fine and singular aspect of some of these noble Eryngiums, when at the Garden of Plants last spring. There they seem to stand the winter with a good bed of litter round the base of the stems. Doubtless, they would do well in our southern counties. In any case the species figured above, and some of the other kinds are worthy of a place in gardens.]

A New Station for Mackay's Heath (*Erica Mackayana*).

—Hitherto this rare Heath has been observed only in the vicinity of Craiggamore Hill, and thence westward along the road leading to Clifden. It will, therefore, be interesting to record a second Irish locality, which is situated about eight miles to the south of Craiggamore. On August 31st I found *Erica Mackayana*, in its most typical form, growing in moderate abundance a little east of the newly-built police barrack at Carna. Here it grows in fair quantity along with the mountain heath on the way to Lough Sheelagh, and is, as usual, associated with *Erica Tetralix*. On the same ground I gathered some of the forms which appear intermediate between *E. Mackayana* and *E. Tetralix*, and which seem to give some reason for uniting the two plants. These intermediates are much more plentiful about Craiggamore and are very variable, forming, as it seems to me, a nearly complete series from *E. Tetralix* to *E. Mackayana*.—A. G. MOORE, in *Journal of Botany*.

Cattle Poisoned by Meadow Saffron.—The appearance of a mysterious disease caused great alarm and much loss recently, in Kilbride, in the district of Ballinrobe, Co. Mayo, where not less than twenty-three head of cattle belonging to six or seven small farmers, succumbed to the narcotic effect of the alkaloid principle of *Colchica*, in which Meadow Saffron (*Colchicum autumnale*) abounds. When the mortality began to assume serious dimensions, it was feared by the people in the locality that an epizootic disease had visited them. The mysterious disease was at once unveiled by a member of the efficient staff of Veterinary Inspectors attached to the Governmental Department of Cattle Inspection, instituted to carry out the provisions of the Contagious Cattle Disease Act. That gentleman, on examining the symptoms of the disease, looked for the cause, and found it in the abundance of the above weeds growing in pastures. A decoction of this plant is used medicinally to allay the pangs of neuralgia, gout, and rheumatism, by external application. The seeds and balms contain most of the acrid principle, and it is, therefore, when in a state of perfection, the plant is most noxious.

A New Application of the Marsh Mallow.—Gypsum mixed with 4 per cent. of powdered Marsh Mallow root will harden in about one hour, and can then be sawn or turned, and made into dominoes, dice, &c. With 8 per cent. of Marsh Mallow, the hardness of the mass is increased, and it can be rolled out into thin plates, and painted or polished.

NOTES OF THE WEEK.

— THE Botanic Gardens in the Regent's Park fortunately escaped the late great gunpowder explosion with the exception of the loss of a few panes of glass (in the corridor), though in Sir F. Goldsmid's close at hand, £50 worth of glass has been broken.

— M. LINDEN, of Ghent, has founded a new establishment at Pallanza, on the shores of Lake Maggiore, in association with an able and well-known amateur, M. le Marquis della Valle de Casanosa.

— THE directors of the Alexandra Palace Company have decided to open the new palace with a grand musical performance on Saturday, the 1st of May, 1875. It is stated that the building is now rapidly advancing, and that the decorations of the interior are nearly complete.

— CO-OPERATION seems to be extending itself even to gardening. Mr. Thomas Hughes presided, it is said, the other evening at an important conference of the friends of co-operation from London and various provincial towns. The principal topic discussed was the application of the co-operative principle to market gardening.

— THE Agricultural Society of France has offered prizes of 1,000 francs each for the best method of artificial irrigation, for the best means of destroying the *Phylloxera vastatrix*, for the best economical means of utilising the Beetroot and its products, and for the educational establishment which shall have taken the best means to instruct in agriculture and horticulture.

— THE gathering of Peaches at Montreuil, in the environs of Paris, is now drawing to a close. The year has been an exceptionally good one, and the value of the crop is two millions of francs. That sum will astonish no one, when the fact is remembered that there are 600 growers at Montreuil, who raise nearly sixty millions of that fruit. For more than a month 500,000 arrive every morning at the central markets.

— MR. MEEHAN, in a recent paper, referred to some Potatoes exhibited by him, in which the stolons of a Grass had penetrated through from one side to the other, preferring, as it would seem, to go through such an obstruction to turning aside to avoid it. He lately exhibited a similar case, only the obstruction was the round smooth root of an herbaceous Peony. Though not more than one-third of an inch round, a stolon of *Triticum repens*, the common Couch Grass, had pushed itself through.

— THE Fungus meeting, held at South Kensington, on Wednesday last, was well attended, and the beautiful colours of many of the species exhibited were much admired. We have now many excellent works on the subject of Fungi, both edible and poisonous, and it is much to be regretted that knowledge amongst even educated people with respect to this interesting class of food-producing plants is so limited. Some years ago, Mr. W. G. Smith, published two valuable coloured charts of most of the common edible and poisonous species, and these ought to find a place in every school-room. Something of this kind is done in Sweden and other countries, and if the same attention was paid to such matters in this country, we would hear less of "Mushroom poisoning" than we now do.

— THE committee of inhabitants of Soho Square have decided to postpone availing themselves of Mr. Grant's offer to lay out the Square at his own expense, or to open it at all to the public until the ensuing spring. The feeling at present amongst the householders is that as Leicester Square, which is the only public garden at present open in the metropolis, has not stood the ordeal of a London winter, it is not advisable to carry out a similar experiment until this has been tested. Another objection has also been raised by a section of those interested, and that is that if Soho Square is to be, in a great measure, as Leicester Square has been through the summer, simply a place of resort for the children of the neighbourhood, who would crowd the seats and prevent those most entitled to enjoy the benefits of the improvements from so doing, under those circumstances it would be better to keep the square in its present form for the benefit of those who have a legal right to use it. That is to say, in substance, lest the poor children should play in it, rather than in the crowded and dangerous streets, let us leave it to the deal cats, and in its present deserted condition.

— INSECTS are destructive enough with us; but it is in other climes that the destruction they may bring is most seen. A lady writing from Kansas to *Moore's Rural* says:—"On the 26th of July, down came an army of those hateful grasshoppers, devouring all that was left. Our young trees, the fruit and shade we hoped some day to enjoy, as well as our hedges and shrubbery, have also fallen victims to their ravages. I fought for those plants you sent me last spring, covering them with papers, tying down as firmly as possible, but the wind would tear them off. The pests have left us twice, but are back again. An unsuccessful fight was made to save a few Geraniums, Verbenas, and similar plants." Great misery results from these visitations. When we visited Salt Lake, the principal nurseryman there had been

ruined by the grasshoppers eating all his stock; a piece of ground with cultivated crops in those arid regions is a happy feeding ground for these small pests. They, however, soon make a desert of it also."

— MESSRS. WARNE have just issued a new edition of their English translation of Alphonse Karr's "Tour round my Garden." It is well printed and illustrated, and in every way worthy of the author.

— POLYMNIA GRANDIS, a stately and noble-looking plant, of which a good figure appeared in THE GARDEN (Vol. VI., p. 115), is in superb condition in Battersea Park this season, where it seems to thrive as freely as any other plant, hardy or tender.

— WE learn from the *Illustration Horticole* that the handsome evergreen, *Torreya myristica*, is now bearing fruit—it is supposed, for the first in Europe—in the nurseries of Messrs. Thibaut & Keteleer, at Secaux, near Paris.

— A GREAT International Show of Fruit and Flowers is to be held under the auspices of the Royal Caledonian Society in Edinburgh, on the 15th and 16th of September next year, when £700 will be offered in prizes.

— A FINE specimen of the variegated variety of Aloe-leaved Yucca, is now in flower at Mount Anville Park, near Dublin. The spike, although only half developed, measures nearly 3 feet in height, and has now expanded dozens of beautiful creamy-white flowers, forming a striking and beautiful object.

— MASSACHUSETTS papers report that a portion of Winchendon—covered with Grass, Cranberry plants, Whortleberry bushes, and over 400 trees—recently floated off into Monomoneck Lake, between Rindge, N. H., and Winchendon, Mass. The new island consists of 6 acres, and is in a lake covering an area of 2,500 acres. It was probably started from its natural site by the lake being unusually high and a strong southerly wind prevailing.

— THE *Pays de Caux* says:—"The crop of Apples in Normandy is decidedly more abundant than was supposed at the commencement of the season. The rates are not yet fixed, but some large lots have already been sold at from 1 franc 50 cents. to 1 franc 75 cents. the half hectolitre (1½ bushel) for early fruit, delivered at once. Many trees are breaking down with the weight of the crop because care has not been taken to prop up the branches.

— A BRANCH of industry which is gradually increasing in importance has arisen in late years in the barren moorlands of north-western Germany, by the preparation of peat (or turf), which is largely used as fuel in that part of Europe; and two companies have lately been formed in Oldenburg for the purpose of manufacturing peat on a large scale. The peat is cut out of the soil of the marshy moors or bogs by means of a large flat-bottomed steam-vessel, which is able to cut a canal 20 (German) feet in breadth and 6 feet in depth, whilst proceeding at the rate of from 10 to 12 feet per hour.

— THE ravages of the *Phylloxera* in the European and American Vineyards are carrying terror even to the antipodes, as may be inferred from the following official announcement:—"It is hereby notified for general information that the Governor of the Colony (Victoria), with the advice of the Executive Council, and in accordance with the provision of the Act 37 Victoria, No. 457, has prohibited the importation into Victoria of Grape Vines and Grape Vine Cuttings.—ARCHIBALD MICHIE, Agent-General for Victoria. No. 8, Victoria Chambers, Westminster, October 1, 1874." The growth of the Grape and the manufacture of wine have made such progress in the Australian colonies within the last few years that it would be a pity if this source of wealth were injured.

— WE are requested to announce that the Commissioners of her Majesty's Works intend to distribute this autumn, among the poor inhabitants of London, the surplus bedding-out plants in Battersea, Hyde, the Regent's, and Victoria Parks, and in the Royal Gardens, Kew, and the Pleasure Gardens, Hampton Court. If the clergy, school committees, and others interested will make application to the superintendent of the park nearest to their respective parishes, or to the Director of the Royal Gardens, Kew, or the Superintendent of Hampton Court Gardens, in the cases of persons residing in those neighbourhoods, they will receive early intimation of the number of plants that can be allotted to each applicant, and of the time and manner of their distribution.

— THE question of the best means to be employed for the conservation of woods and forests in Germany came before the foresters' congress held at Freiberg, on September 5. The importance of the subject was universally admitted, and the extraordinary influence which a scientific and systematic method of management would have on the general physical and economic relations of the people at large was fully recognised. In Germany about 18 per cent. of all the woods are in the hands of communal and parish proprietors, and only 4 or 5 per cent. in those of the Imperial Government; hence, until legislative enactments are brought to bear on this branch of landed property, no uniformity of system can be looked for. The next meeting of the congress will be held in 1875, at Hanover.

THE INDOOR GARDEN.

THE FLAMINGO PLANT.

(ANTHURIUM SCHERZERIANUM.)

OF all the species belonging to this singular genus this is, perhaps, the most strikingly beautiful. It comes from Costa Rica, and has, as most of us know, a large scarlet spathe, and a twisted spadix, which when elevated, as they are, on a tall peduncle, have a peculiar aspect, and have gained for this species the name of Flamingo plant. The accompanying illustration has been prepared from a photographic representation of one of the finest specimens of this plant to be found, perhaps,

opportunity should miss visiting his grounds, where they will see curious birds and animals, as well as plants.

Clovenfords.

WM. THOMSON.

Second-year Guernsey Lilies.—What is the proper treatment for Guernsey Lilies, after they have done blooming, to ensure their flowering again the following September?—H. LITTLEWOOD, *Stour-bridge*. [This showy autumn-flowering Amaryllid has never been very extensively cultivated in this country owing, doubtless, to the fact that, under the ordinary mode of treatment, the bulbs are of no further use after flowering; and hence a supply has to be purchased annually, incurring a considerable expense, for the bulbs have always been comparatively costly. There is, however, no good reason why

The Flamingo Plant (*Anthurium Scherzerianum*). A specimen grown by Dr. Paterson, Bridge of Allan.

in Europe, and it is also one of the best varieties of this truly useful species. It was purchased, when a small plant, by its present proprietor, Dr. Paterson, of the Bridge of Allan, from Messrs. Veitch, of Chelsea, and is now growing in the largest sized pot that is made. The compost in which it has thriven so well, consists of peat, charcoal, broken crocks, and Sphagnum. The pot is half filled with drainage. The temperature it has all along been grown in is intermediate between that of a stove and a greenhouse. Dr. Paterson is a great horticultural enthusiast, and has done much to disseminate a taste for plants, especially Orchids, in Scotland. Of the latter he is a very successful cultivator, and his advice and example have led many to form collections of these interesting plants. His stoves and greenhouses are open to all visitors, and no one who has the

necessity for these annual outlays should continue; for, with proper treatment, the bulbs will flower year after year, and produce a plentiful crop of offsets. The bulbs should be procured early in September and planted at once, say three in a 6-inch pot, using light sandy soil in a moist healthy state, and the pots should be placed in a cold frame near the glass, or on a front shelf of a greenhouse, or wherever they may be likely to receive abundance of light and air. Growth will commence at once, and the soil should be kept properly moistened, and the flower-stems supported by neat stakes. While in bloom place them in a dry, cool, airy situation, and give a liberal supply of water. When the beauty of the flowers is over, instead of starving the bulbs in the handful of soil in which they have been blossomed, as is usually done, have ready a box 12 inches deep and of a convenient size, in which to plant them in the following manner. Having first properly drained the box by placing in the bottom an

inch of broken potsherds, covered with a layer of turfy pieces of soil, and having a quantity of good, fresh, nicely broken up, sandy loam at hand, turn the bulbs out of the pots, and single them out with as little injury as possible to the few roots they may have. Plant them in rows 6 inches apart and 6 inches asunder in the rows, spreading out their roots in as natural a form as can be done, keeping the crown of the bulb about level with the surface of the soil, and this as high as the edges of the box. Give a gentle watering after planting, with a view to settle the soil, and place the box in a cold frame near the glass, or where more convenient, provided a temperature of 40° can be maintained, with plenty of air on mild days. The necessary attention during winter will be simply that required for greenhouse plants generally. Managed in this way the space occupied will not be very considerable, and it is evident that there will be ample room for the roots, and every necessary condition towards the growth and ripening of the bulbs. When the foliage shows indications of decay, which will be the case towards the middle or latter end of April, gradually discontinue water, and when the leaves die off, either take up the bulbs and store them in a dry place, or remove the box to a cool dry situation until the proper season for encouraging growth has arrived. They may be left in the box to flower, or potted in the usual manner. It will be necessary, however, to transplant every second or third year, otherwise the bulbs will be too close together, will be imperfectly matured, and, in consequence, will flower weakly.—J. S.]

THE FLOWER GARDEN.

NOTES ON BEDDING PLANTS AROUND LONDON.

My notes on bedding plants, taken in London parks and gardens, may, perhaps, be useful to others as well as to myself. Starting at the Marble Arch, Hyde Park, and turning to the left, I soon saw that *Stellaria graminea aurea* was out of place under trees, being weak and green-looking. Further along I met with a fine bed consisting of *Coleus Verschaffeltii* in the centre, and here and there, at equal distances apart, the beautiful new *Abutilon niveum aureum maculatum* rising above the *Coleus*. In the three outer rows were *Centaurea ragusina*, *Pelargonium Crystal Palace Gem*, and *Mesembryanthemum cordifolium variegatum*, the yellow and silver colours blending charmingly together. The next had I noticed had *Pelargonium Bonfire* in the centre, surrounded by *Verbena Sportsman*, and edged with *Stachys lanata*, altogether a bright and effective bed. A very fine mass of *Pelargonium Madame Moirier*, next caught my eye; it has a fine bright pink colour, its trusses are very large, and it is a free bloomer. Then came beds of *Pelargonium Pioneer*, bright ruby-crimson, and *Vesuvius*, a bright scarlet. Looking down the whole length of the floral border by the side of Park Lane, the effect was strikingly beautiful. One thing, however, will not bear close inspection, and that is the mud banks, to which you have often alluded; the sooner they are abolished the better. In another part of the park I saw a remarkably fine bed of *Erythrina laurifolia*, producing fine spikes of bloom, but somewhat dull in colour. A pretty *Lobelia*, named *Blue Bonnet*, round a bed, looked so like *Lustrous* that I could not see any difference between them. In what is called "The Dell," I noticed *Pelargonium Bonfire* and *Glow* in fine condition; also a pretty bed of *Pelargonium Albion Cliffs*, a white variety, mixed with a *Blue Viola*, and margined with *Mesembryanthemum cordifolium variegatum*, a combination which I considered extra good. Of the cottage, one of the prettiest little spots about London, you have given us excellent illustrations. Round its front (see p. 301) are several circles, consisting of three rings, with a *Centaurea ragusina* in the centre of each; next comes *Lobelia Blue Bonnet*, then *Alternanthera amœna*, and *Pyrethrum Golden Feather*, with a straight row of *Cineraria maritima compacta*, connecting one ring with the other; of two margins, the inside one consists of *Pyrethrum Golden Feather*, and the outer one *Echeveria glauca*; a narrow line of *Pachyphytum bracteatum* runs through the centre crossways, and the rest is filled in with *Alternanthera amœna*, *Mesembryanthemum cordifolium variegatum*, and *Alternanthera magnifica*; the two different shades of yellow in this border harmonise beautifully together. At each end is a select piece of small sub-tropical plants in the border. There is only one fault, and that is, the *Centaurea* has grown too luxuriantly. The beautiful cut-leaved *Cineraria cœratophylla* would have been in better keeping with the rest of the arrangement. In the centre, near the door-way, a half-moon bed of *Pelargonium Shakespeare* had an effective appearance, margined with rows of a bicolor *Zonal*, *Blue Lobelia*, *Stellaria graminea aurea* and *Echeveria glauca*; two circular match-beds being filled, one with *Pelargonium Queen of Queens*, and the other with *P. Daybreak* mixed with blue

Viola. The next rows consisted of *Pelargonium Crystal Palace Gem*, *Alternanthera amœna*, and *Lobelia Lustrous*, margined with *Stellaria graminea aurea* and *Echeveria glauca* alternately. Both these beds were very effective, backed up, as they were, with *Pelargoniums*, *Palms*, and similar strikingly pretty plants. In front of the palace in Kensington Gardens I noticed a large bed of *Pelargonium Shakespeare*, banded with *Verbena Purple King*, and margined with *Stellaria graminea aurea*—a remarkably bright and telling combination. In the Duke of Teck's garden were several heart-shaped beds, the centres of which consisted of white-edged *Pelargoniums*, banded with *Lobelia Blue Stone* (a fine dark violet self), and margined with *Stellaria graminea aurea*. These beds were all well planted, and looked very gay. In the trial ground I noticed a fine *Pelargonium*, called *Edward Sutton*—a kind with large bold trusses, and dark crimson, but yet bright-looking, flowers.

In Battersea Park the mound of *Antennaria tomentosa* does not seem so well covered as I have seen it in former years, a circumstance doubtless attributable to the dry hot weather through which we have just passed. Here I noticed a fine plant of *Aloe mitriformis*, bearing a large bunch of scarlet flowers, much resembling those of a *Blandfordia* in shape, but smaller and more numerous. Here the double-flowered variety of *Lobelia pumila grandiflora* was a failure. The carpet beds, which were in the panelled style, were bright, well contrasted, and well planted. The centre panel, consisting of *Alternanthera paronychioides major*, had a fine orange tint, and at each end was a kind of heart-shaped panel planted with *Alternanthera amœna*, surrounded by a good belling of *Pyrethrum Golden Feather*; next came a broad piece of *Alternanthera amœna*, then a row of *Kleinia repens*, with its peculiar glaucous blue tint, the whole being margined with *Sempervivum tabuleforme* and *Sedum glaucum*. This, and a larger bed planted in the same way, were fine examples of this style of bedding. The next beds which attracted my attention were a pair of half-oblongs, as they are termed, separated by a circle; the centres of the long beds were filled with two varieties of silver-margined *Pelargoniums*, one with cerise-coloured flowers, the other with white blossoms; then came rows of *Alternanthera paronychioides major*, *Mesembryanthemum cordifolium variegatum*, *Alternanthera magnifica*, the whole being edged with *Mesembryanthemum cordifolium variegatum*. The circle contained *Pelargonium Lass o' Gowrie*, which did not look at all well; it should have been planted with *Cineraria maritima compacta*. The next row was *Lobelia pumila grandiflora*, margined with a double row of *Echeveria glauca*, a good combination as regards colour; a round bed of *Fuchsia Sunray*, full of bloom, intermixed with a light blue *Lobelia*, had a pleasing appearance. I also noticed a bed of *Heemp* (*Cannabis gigantea*), 12 feet high; this, I think, always looks best as a single specimen; *Pelargonium Amaranth*, with *Centaurea ragusina* round it, was very effective. Among sub-tropical plants, *Polymnia grandis* is certainly one of the very finest, and an oval bed with a centre consisting of *Vitis heterophylla variegata*, with a few plants of *Grevillea robusta* rising above, belted round with *Lonicera aurea reticulata*, was very effective; *Alternanthera magnifica*, edged with three rows of *Echeveria glauca*, was also lovely. There was, moreover, a large raised circular bed, the centre of which consisted of *Coleus Verschaffeltii splendens*, very bright in colour, surrounded with *Cineraria maritima compacta*, *Pyrethrum Golden Feather*, *Aloe attenuata*, and edged with *Echeveria pumila*. The raised border near the refreshment room I found very effectively planted with masses of *Stellaria graminea aurea*, broad bands of *Lobelia pumila grandiflora*, margined with three rows of *Echeveria glauca*, and filled in between with *Sedum glaucum*, the whole backed up with *Fresino Lindeni* and *Zonal Pelargoniums* in bloom.

In St. Stephen's Square, Westminster, were some large beds filled with *Pelargoniums* and edged with *Lobelia pumila grandiflora*, which certainly looked well, considering the many drawbacks to which their position subjects them. In front of the Houses of Parliament too, I noticed some fine beds of *Cannas*, edged with a pretty reddish-lilac coloured *Lobelia*, called *Omen*. In Victoria Park, entering, by what I think, is called the Hanover Gate, and turning to the right, the eye soon rests upon some elaborate carpet beds, consisting of a semi-circle with a *Tricolor Pelargonium* in the centre, banded with *Amarantus melancholicus ruber*, semi-circle of *Echeveria glauca*, edged with *Stellaria graminea aurea*, clipped, and in splendid order. A magnificent piece of scroll work next attracted attention, the groundwork of which was *Alternanthera amœna* spectabilis, with small masses, at equal distances apart, of *Coleus refulgens*, *Alternanthera amœna*, *Coleus Verschaffeltii*, surrounded with *Pyrethrum Golden Feather* and *Mesembryanthemum cordifolium variegatum*. There were several small circles of *Mesembryanthemum* with one plant of *Sempervivum tabuleforme* in the centre of each, the whole being edged with a double row of *Echeveria glauca*, a chaste and good arrangement. Along what is termed the Drive, I observed some fine circular beds of *Verbena Purple King*, also a good

scarlet *Tropæolum*, a seedling not yet named. The double-flowered variety of *Lobelia pumila grandiflora* is here, as elsewhere, a failure, spoiling some of the principal corner beds. I saw, moreover, some very fine round beds filled with white-edged *Pelargoniums* and *Viola Admirata* (a superb variety) mixed together, the whole being edged with *Pyrethrum Golden Feather*; these looked cheerful and pretty. Next came a sort of double kite-shaped bed, with two small circles for effect. The centre of this consisted of *Alternanthera amœna spectabilis*, next *Pyrethrum Golden Feather*, then a broad band of *Alternanthera magnifica*, edged with two rows of *Echeveria glauca*. The small circles consisted of *Mesembryanthemum cordifolium variegatum*, edged with *Echeveria glauca*, a mass of *Cerastium tomentosum*, at each end, being dotted into the *Alternanthera magnifica*. This is a very rich-looking faultless combination. One of the finest mixtures in the park, however, consists of a Maltese cross, formed of *Cerastium tomentosum*, supported by *Pyrethrum Golden Feather* and *Alternanthera amœna spectabilis*, very highly coloured; the three outside rows being *Mesembryanthemum cordifolium variegatum*, *Alternanthera magnifica*, and two rows of *Echeveria glauca*, the whole making a charming bed. A large round bed, with a star and triangles to match, also looked strikingly effective. The centre consisted of a dark-leaved *Colens*, next a broad band of *Pyrethrum Golden Feather*, the next row and the spikes of the star being *Alternanthera amœna*, resting upon a fine piece of *Echeveria glauca*. The triangles were planted with *Alternanthera amœna*, with a border of *Pyrethrum Golden Feather*, the two outer rings *Alternanthera magnifica*, and two rows of *Echeveria glauca*. This appeared to be a faultless arrangement. The rockery, a beautiful spot, is covered with *Sedum glaucum*, and dotted all over with such plants as *Fuchsia Golden Treasure*, *F. Smiley*, *Stellaria graminea aurea*, *Sempervivum tabulaforme*, *Sedum acre elegans*, *Yucca aloefolia variegata*, *Portulaca grandiflora*, *Viola cornuta*, *Salvia argentea*, *Tussilago Farfara variegata*, *Eucalyptus globulus*, *Zea variegata*, *Agave americana variegata*, *Sedum F. spectabile*, *Centaurea Clementii*, *Echeveria metallica*, *Sempervivum arachnoideum*, *Kleinia repens*, *Dracœna ferrea*, *Pachyphytum bracteosum*, *Cotyledon spinosum*, *Amicia zygomeris*, *Pyrethrum Golden Feather*, *Sempervivum Bolli*, *Echeveria metallica glauca*, *Wigandia caracasana*, *Chamæpseudea diacantha*, and others.

R. H. B.

THE HELIOTROPE.

AMONG sweet-scented flowers the *Heliotrope* has long held a high position, both as a pot plant for conservatory decoration, and also as a fine plant for bedding purposes. Ten and fifteen years ago, beds of *Heliotropes* were to be found in every garden; they were grown not so much for display as for their soft beauty, their rich fragrance, and their continuous blooming character. A bed of *Heliotropes* is a rarity nowadays; even in catalogues they are now found under the head of miscellaneous bedding plants, instead of being prominently put forward, as we can well remember their being some years ago. Nevertheless the *Heliotrope* has been undergoing a certain amount of improvement year after year. Certain raisers on the Continent have been turning their attention in this direction, and with marked success; such improvement, however, has been confined to the production of seedlings with larger flowers and bolder tints, without much variation in the colour, which ranges from a delicate greyish-lilac to a black-purple. The *Heliotrope* is a plant that, while admitting of much variation of the particular hue seen in the flowers, yet does not break from a certain monotony of colour found in the several varieties. The old-fashioned gardener, as we are apt to term him, still plants out his beds of *Heliotropes* in order to assist the summer display, and rejoices in the rich harvest of cut flowers which they afford him; the modern gardener rarely or never. The late springs of recent years have done something to bring the *Heliotrope* into disrepute, owing to its tender character. It is a plant so sensitive of frost as to be quite cut down and disfigured by a slight visitation from this unwelcome guest in early summer. An early frost in September will lay low the beauty of many a bed. Gardeners propagate the *Heliotrope* by means of cuttings put in in August, and again in spring. For all ordinary purposes spring-struck cuttings are the best, especially where there is restricted accommodation for wintering the plants. If some good specimens were wanted for growing in pots for conservatory decoration, then the cuttings should be taken in July or August, choosing for the purpose the terminal shoot of some of the most luxuriant plants, and preparing the cuttings by cutting them through close under a joint. Insert a few round the sides of a 48 or a large 60 pot, and place them in a frame, and shade them from the sun. Bottom heat is not requisite for striking purposes at this season of the year. The cuttings soon make roots, generally in two or three weeks, and they begin also to make vigorous growth. They should then be potted off

singly into 60 pots, using a compost made up of light fibry loam, sandy peat, and well decomposed stable manure, such as that from a spent dung bed which has become somewhat dry under the influence of the summer's sun. As the plants fill the pots with roots they must be shifted into larger sized ones, in which they can remain during winter; and when they have received this last shift, the plants may be placed out of doors to ripen their growth and harden their wood previous to wintering them. They should be placed on a dry shelf near the glass in a greenhouse, where they will be out of the reach of harm from frost, and receive just enough water to keep them alive. In the spring, when young growth begins to appear, the plants should be turned out of the pots, the balls slightly shaken out and any worms removed, and re-potted into fresh soil of a character like that recommended above; and the branches should be shortened back with a knife, so as to lay the foundation for nice bushy plants. In the month of May give another shift, according to the size of the plants and requirements of the roots, and thus fine specimens will be formed that will bloom in the conservatory for many months, and if judiciously managed, yield flowers through a great part of the winter. Another mode of propagating is to lift a few plants from the beds in the open ground at the end of August, pot them, and winter them in a temperature of 45° to 50° if possible, and then put them into a brisk heat in early spring, where they will break into a profuse growth, and supply plenty of cuttings, that can be struck in the same way as *Verbenas* and *Petunias*, potted on, and made to grow rapidly and vigorously. As a rule flower gardeners prefer plants that have been struck from cuttings, early in spring, in this fashion. When bedded out the *Heliotrope* should be planted in a good soil, or, as one of our fine old gardeners puts it, "in soil that is well charged with rotted dung." First comes a free and luxuriant growth, and then, during the whole summer and autumn, as long as favourable weather continues, a profusion of gay and odoriferous blossoms. The following varieties can be well recommended: *Etoile de Marseilles*, pale, very large and fine; *Jaune Dumesne*, dark, very good, and striking; *Jean Amour*, delicate in colour; *Mons. Cassanave*, purple, very fine; *Mrs. Lewington*, shaded purple; a fine bedding variety; and *Souvenir de Leopold I.*, light lavender-lilac, very dwarf and free.

R. D.

TROPÆOLUM LOBBII.

UNDER judicious management, this *Tropæolum* may be had in flower all the year round, *i.e.*, where plants of it are grown for that purpose. It likes a rich, deep, friable loam; a stiff adhesive soil does not suit it, and when planted in such material it soon loses its under leaves, and becomes unhealthy and shabby in appearance. If the soil is naturally stiff, it is well to add to it some coarse sand and some well-rotted manure. When planted in a bed in the flower garden, it often proves a good plan to lay some neat branches flat upon the bed on which the plants run, and are kept just clear of the soil, as, although they like a good supply of moisture regularly, they are somewhat impatient of it when allowed to lie flatly upon a damp surface. This *Tropæolum* is very easily increased by means of cuttings, put in in the usual way. For winter flowering, I used to put eight or ten cuttings into a 6-inch pot; these were made of the youngest growths, which, in general, are too soft and too liable to damp off; nor is it well to take cuttings from the older parts of the stems, as it is but seldom they will grow. A few joints back from the points make the best cuttings. For winter flowering, let them be put in any time during the summer months. If struck in July or in August, with care, they may be had in flower in succession all through the winter months. They may be grown either singly in small pots or in large ones, according to the space and accommodation at command. They do not require much heat; a temperature of 45° or 55° suits them well, but they should have air upon all favourable occasions. Under judicious care and regular attention it is highly interesting to see how useful and accommodating such slender plants as these may become. I have often had them doing good service in both the greenhouse and conservatory in very different shapes and forms; sometimes when the cuttings had been rooted in nearly all sand, I have shifted them undisturbed from the cutting-pot into the centre of a much larger pot. The soil best suited for them when in pots consists of two parts friable loam and one turfy peat or leaf mould, adding sand to improve the texture, and to allow the fine roots free liberty to run where they liked. Whatever sized pots are used let them be thoroughly clean; and, having secured good drainage, fill them up in the usual way. I have had two or three plants in an 8-inch pot in excellent condition for months during winter and early spring. I have transferred six plants from a cutting-pot to a 10-inch one, planting at equal distances apart, and very near the side of the pot; then, after putting a few nice Willows or young Hazel sticks round the inside of the pot, gather their tops

together and tie them at 18 inches or 2 feet in height, so as to form a trellis, which may be either balloon-shaped or pyramidal, according to taste. As soon as the plants have acquired sufficient size let them be tied on this support regularly one after the other in a somewhat spiral manner, but taking care that the under portion of the trellis is well-furnished before the top. These shoots will often grow some time ere they begin to flower, and yet cuttings in general flower pretty soon after they have once started into free growth. Besides this way of training, I have had this *Tropæolum* in different shapes. The top of some young tree makes a good support for it; place it firmly into the middle of the pot, and train the young growths up the stem; as they progress, guide them to the outer points of the branches, which they will in time regularly cover, and thus form a miniature tree. When well grown, this *Tropæolum* looks well on the dinner table; but, for that purpose, it must be grown in small pots, and be otherwise well attended to, so as to be covered both with nice green foliage and red-orange flowers. Cut sprays of it in damp sand, placed round the edges of small vases, or epergnes, also look well in connection with fronds of Maiden-hair Fern, or anything similar in character. For flower garden work, spring-struck plants are best.

G. DAWSON.

AUTUMN CROCUSES.

THE following Crocuses are now flowering in my garden. I give the approximate dates at which they first opened:—Sept. 18. *Crocus speciosus*, the finest of all the autumnal species; stigma, bright orange red. *C. ibiricus autumnalis*, of Continental gardens, is in no way different from this. Sept. 22. *C. nudiflorus* (pyrenaicus), a very fine large purple species; stigma, yellow. I have also a small one, brought by Mr. Maw, from central Spain, which appears to be the same, though not half the size. Sept. 22. *C. Boryi*, small but very pretty; white, with yellow throat; anthers, white; stigma, yellow; the three outer petals are lilac exteriorly; but, in a variety I found in the island of Syra, which flowers later, they are veined only with lilac. Sept. 23. *C. serotinus*, lilac, leaves appearing after flowers. Sept. 25. *C. Salzmanni* (tingitannus), is put down by Mr. Baker as a variety of *serotinus*, but, in my plant, which came from north Africa, the leaves appear rather before the flowers, and are now several inches long, whereas those of *serotinus* are just showing. Sept. 26. *C. cancellatus*, lilac; if my specimen, which I had as *C. Spremeri* is true, it hardly differs in flower from *serotinus*, except that the stigma is rather more deeply divided. Sept. 29. *C. peloponnesiacus* (Orphanides), pure white; stigma, red; anthers, lemon colour; very pretty. Sept. 29. *C. byzantinus* (iridiflorus), deep lilac; stigma, lilac; anthers, lemon; easily distinguished by the three inner segments of the limb being much smaller than the outer ones, and not exceeding the anthers. Oct. 4. *C. longiflorus* (odorus), pale lilac, with yellow throat; stigma, red; anthers, yellow; leaves with flowers, if my plants are true, as I have no doubt they are, though Mr. Baker describes the leaves as coming after the flower; scent, faint. Oct. 5. *C. medius*, dark lilac or purple; stigma and anthers, yellow. *C. sativus* has leaves about an inch long, but does not yet show flower. Besides these I have—*C. Thomasi*, *C. hadriaticus*, and *C. Visianicus*, which will flower later. If any other autumnal species are grown in this country I should be glad to hear of them, especially any with yellow flowers.

H. J. ELWES.

THE BELLADONNA LILY.

IN addition to the representation and account of this Lily, which you have given at p. 113, allow me to say a few words:—This showy and truly splendid bulb has, I fear, not been treated with that attention which its merits as a late autumn flowering bulb deserve. It is true that we may here and there see a few imported plants of it in flower in pots, decorating the greenhouse or conservatory at this season; but they afford but a poor idea of the gorgeous flowers which this Lily produces when cultivated out-of-doors. About twelve years ago I had a number of imported bulbs, and after they had blossomed in pots they were planted out close to the front wall of a greenhouse, but they had no more protection there than they would have had at the bottom of any south wall. The holes in which they were planted were about 18 inches deep, and wide in proportion, 4 feet apart, and filled up with good sandy loam. In these holes four bulbs were planted, 1 inches deep; they were then covered with 10 inches of leaf mould in a conical form; they remained in this condition during the winter. As spring advanced I stirred and removed a portion of the leaf mould, in order that the heat from the rays of the sun might penetrate to invigorate the languid and blanched foliage, which at that season makes an effort to reach the genial air. This should be done until the bulbs are within 4 or 5 inches of the surface. If the weather is dry and warm let them have some good waterings, with a

view to encourage a rapid and strong growth of the foliage. Care should be taken that no plants of tall growth be planted in front of them to shade their foliage from the full effect of the meridian sun, nor a leaf removed until the ripening process has been fully accomplished, which, in favourable seasons, will be about the beginning of August. It was not until the third year after planting that these bulbs flowered with me. They are impatient of removal, and therefore the greatest care should be taken when offsets are removed not to interfere with the general mass of bulbs. When once established they produce offsets freely and flower abundantly, so much so that I have now, October 3, masses of them in full bloom, containing from twelve to eighteen flowering stems, with from eight to twelve blooms in each umbel. About the first week in September let the ground be stirred deeply around the bulbs without interfering with their roots, and thoroughly watered with weak manure-water once or twice. This will induce activity, and accelerate the protrusion of the flowering-stems. One objection may be made against these Lilies, and that is, that they are without foliage during their blooming period; but this may be greatly obviated by planting them in alternate patches with the *Jacobaea Lily*, which flowers splendidly in mid-summer, and whose fine green foliage will be in perfection during the flowering season of the *Belladonna Lily*.

M.

The Bulbs of Lilies.—Most of the Japan Lilies continue to produce flower-stems from the same bulb, but, by a close examination, we find that the flowers stalks spring from new bulbs, formed within the old bulb every season. They are in fact new bulbs formed within the parent one, but remain attached to the same base, drawing in part sustenance from the surrounding scales, which are only undeveloped leaves. The common wild Lilies, such as *L. superbum*, *canadense*, and *philadelphicum*, found growing in low meadows almost everywhere, are, according to a correspondent of *Moor's Rural*, perpetuated in quite a different manner. The bulbs are produced on large subterranean stems growing a few inches below the surface of the soil. This stem lengthens just sufficient to admit of a new bulb every year, the one formed the previous season blooming but once, then commencing to decay, although it is quite probable that they yield up a portion of their substance to the new one while growing. Very frequently, in digging up one of these white Lilies, we find quite a string of bulbs, of various ages, all attached to the subterranean stem; but the last formed, or youngest, is the only one which will bloom after the transplanting. Other species of bulbs and tubers increase in a different manner, each having peculiarities of its own, although all are obedient to a similar law. If we were to only study that portion of the vegetable kingdom which is seen above ground, one-half would be overlooked, for it is not infrequently the case that the most interesting part is hidden in the earth.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Rose Cuttings.—When should these be put in?—*Rosa*. [Put them in now, having first removed their leaves with the exception of the two end ones, and ent them into 6-inch lengths. Insert them in a shady border, and cover them with hand-lights if convenient, but this is not absolutely necessary, as good plants may be reared without such assistance. Thus circumstanced, they should remain until April, when they will be fit for potting off.—F.]

Autumnal Flowers.—Among hardy flowers noted in Mr. Ware's Nurseries at Tottenham this week, the following are most attractive:—*Aster amellus*, *bessarabicus*, *grandiflorus*, *longifolius* var. *formosus* (very fine), *floribundus*, *crinoides*, and *Neveii*; *Lithospermum prostratum*, *Sternbergia lutea*, *Strumaria crispa*, *Phygelius capensis*, *Androsace lanuginosa*, *Liatris scariosa*, *Anemones japonica* and vars., *Campanula trachelium*, *Colechicums* of sorts, *Convolvulus mauritanicus*, *Stevias* of sorts, and *Cedronella mexicana*.

Phytolaca icosandra.—Most people are familiar with the beautiful tall-growing *Phytolaca decandra*—the "Virginian Poke"—with its long drooping racemes of dark olive or black fruit; but *P. icosandra* does not appear to be so well known. It grows from 2 to 3 feet high, and has a bushy habit, the leaves being similar to those of an *Hydrangea*. It bears longish spikes of rather inconspicuous creamy-white flowers, but it is its fruit which renders this plant remarkable and curious. Imagine a plant with perhaps a dozen stems or so, each terminating in clusters of fruit, similar in size and shape to Indian Corn, but composed, as it were, of ripe Blackberries, and you will have a tolerably good idea of the appearance of this plant at the present time. It is a plant which, when in perfection, is sure to elicit the remark, "Whatever is that?" from all who see it.—THOS. WILLIAMS, *Ormskirk*.

Wintering *Salvia patens*.—What is the best way of keeping tubers of this plant through the winter, and starting and increasing the same in spring.—H. LITTLEWOOD. [Let a dry day be chosen to take up the plants, and let the tops be cut off and the soil shaken from their roots. Lay them for a few days in a shed to dry, and, having procured a box or old tub sufficiently large to hold the roots when packed closely, get some dry sandy peat, finely broken; a layer of the roughest of this, about an inch thick, should be laid at the bottom of the box; the roots may then be packed as closely as possible in layers, and the spaces between each filled with peat. When the box is full, give it a good shaking, and press it well down with the hands, to stop up all the cavities; finally covering the whole about 2 inches thick with the rough part of the peat. The box may then be removed to a cellar or other convenient place, secure from frost, where it may remain without any further care until the following spring. Then unpack, put the roots, and start them in heat, as you would *Dahlia* roots.]

THE GARDEN IN THE HOUSE.

FLOWERS IN HYACINTH GLASSES.

THOSE who may not care to incur the expense of glass stands, or who have no convenience for decoration on an extensive scale, may, nevertheless, produce a pleasing effect by lightly placing a few sprays of flowers in an ornamental Hyacinth glass. In this way such glasses are made to answer two purposes; one being to hold cut flowers in summer; the other bulbs in a growing state in winter. If, when being purchased, this twofold use is borne in mind, it will be better to get them of a more ornamental shape and better quality, than if for growing bulbs only. White and gold, and purple and gold, both produce pleasing contrasts, but there are several other colours of which choice may be made according to taste. When flowers are about to be arranged in such glasses as are represented in the accompanying illustration (for which we are indebted to Mr. Scott, of Merriott Nurseries, Crewkerne), dark and rich shades should be selected for flowers of a light colour, and bright shades for dark flowers. A spray of such a Rose as the Duke of Edinburgh, placed in a crimson-coloured glass embellished with gold looks well, as does also one of Gloire de Dijon, in a purple or dark blue glass; the arrangement in vases of this kind (if I may so term them) need not, however, be limited to one variety of flower. A white or tinted Rose in the style of Souvenir de la Malmaison, with a spray of Dielytra, one or two blue Forget-me-nots, and a few Grasses and Ferns would form a pretty mixture. Some of these glasses may be purchased in the form of three combined, as shown in the accompanying illustration; when such triplets are used, of course, more flowers must be employed in their decoration, such as Roses, Lilies, Sweet Peas, Fuchsias, Pelargoniums, Dielytra, and Ferns and Grasses of various kinds. The smaller vases are well adapted for mantelpiece decoration, or for small tables. The large kinds may be placed in the centre of a table of larger size, or a group may be formed on a side table. For a small breakfast table one of the larger-sized vases would form a pretty centre ornament, with a few small specimen-glasses grouped round it. A pair of such glasses in Etruscan ware, if filled with cut flowers of light coloured shades, would be well suited for the decoration of the buffet, or chimney piece in the dining-room; but like the flowers, the selection of the vases should be left to the decorator's own taste. A. HASSARD.

Flowers in Hyacinth glasses.

ARRANGEMENT OF FRUIT FOR DESSERT.

YOUR correspondent, "W. T. P.," objects to fruit being put on the dinner-table, because "the heat of the lamps, the steam of joints and of made dishes, &c.," have a tendency to spoil its taste. "W. T. P.," seems to have forgotten that neither soups, joints, nor made dishes, are now placed upon the table along with fruits and flowers. The fashion is now *à la Russ*, and the choicest fruits and flowers are required to deck a table laid out in this style. When the joints are carved on a side-table, and quickly removed from the room, they have little influence on either fruits or flowers; and very few made dishes are in fashion; cold *entrées* are now generally used, and even the hanging round of a hot dish does not so quickly affect fruits or flowers as your correspondent imagines. If we are not to place fruits upon the table what are we to put in their stead? Fruits and flowers, neatly arranged and placed upon the dinner-table, have a charming effect, and there is no need whatever to introduce such strong-scented

flowers as Hyacinths, Tuberoses, and Narcissus; in fact, few would allow such flowers to form part of the decoration. "W. T. P." says "Oranges are objectionable on account of their bright colour; but in cases of emergency they might be allowed a place on the table." He forgets, seemingly, that many prefer the smell of Oranges to that of any other fruit; they form, in fact, one of our best dishes during winter, when there is little else that is bright or enlivening; what can look more beautiful than a pair of plates of Oranges when their colour is gently toned down with their own green leaves, matching a similar pair of plates loaded with Apples. Your correspondent appears also to object to Pine-Apples, but can he give us a better ornament for the centre of an *aperçu*? Then he dislikes a Melon; but in dining rooms we use such fruits continually, and without complaint as to their odour, and to banish them from the table would, I think, be a mistake. I object to "W. T. P.'s" mode of serving fruits as one would an *entrée*. The best plan is to place them where they can be seen to the best advantage. In placing fruits upon the table two objects should be kept in view, first, tasteful arrangement; secondly, to use the dessert dishes or service in which they are placed—dishes often possessed of antiquity and interest of other kinds. J. C. H.

Ooley Manor, near Wolverhampton.

Orchids for Vases.—Orchid flowers are most useful, either for hand bouquets, button-holes, or vases. It may be thought that they do not last long, but that is a mistake, as most of them remain fresh for a much longer time than many of our hardy garden flowers. Simplicity, in regard to plants selected for the decoration of vases is much to be commended, but to the use of hardy flowers alone, when tender ones can be had, I quite object. There are few, I apprehend, who would not prefer a vase decorated with sprays of what are termed Bridal Orchids, intermixed with other suitable relieving subjects, whether tender or hardy, to one composed wholly of Harebells, Forget-me-nots, white Water Lilies, Veronicas, and Grasses. These may be within the reach of all, but those who have, or can afford to obtain, the rich waxy and enchanting flowers of some of our

Dendrobiums, Odontoglossums, Oncidiums, Phalenopsis, and others, by an elaborate system of arrangement can, in union with other suitable flowers, Fern fronds, and Grasses, produce a style of vase decoration unequalled by the most elegant composition of hardy flowers alone. If the vases are only required for the night's use, many flowers could be used that could not if they were required to stand for several nights; as, for instance, *Acridas*, *Saccolabiums*, and some *Dendrobiums*—that would be of little service otherwise than wired—could be effectively employed. These may sometimes be advantageously used without wires; but, although graceful in the extreme when growing on the plants, they are too apt to assume a clumsy appearance if used for furnishing table vases unless wired; and, if thus treated, they cannot get moisture to sustain their blooms in that desirable plump condition which they would retain if their stalks were inserted in water or damp sand.—A. H.

Panicum capillare (Eragrostis elegans).—I find this highly ornamental Grass to be most useful for mixing with all kinds of arrangements of cut flowers, its light, elegant miniature plumes lending a grace alike to the choicest exotics and the simplest hardy flowers. By means of this and a few sprays of Fern, even the uninitiated in floral decoration could scarcely fail to produce a charming combination of cut flowers.—JAMES GROOM.

A New Plant for Table Decoration.—*Amarantus Henderi* stands in the first rank of plants for this purpose. We have seen plants of it 2 feet high, with about thirty or forty shoots, forming perfect pyramids 18 inches across at the bottom. Some grow from 3 to 4 feet high. The prevailing colour of this variety is intense rosy-carmine, a fact that may be readily understood when it is stated that *Amarantus elegantissimus* was one of its parents. It is stated at p. 262 to have been a seedling of Messrs. Lamoureux's; that is a mistake; it was raised by Messrs. Hender, whose name it bears, at the Bedford Nursery, Plymouth.—A.

THE FRUIT GARDEN.

STRAWBERRY FORCING IN MARKET GARDENS.

STRAWBERRIES are forced largely in the market gardens around London. For this purpose the strongest and earliest runners are selected, and pegged down on 3-inch pots filled with soil, and plunged in the alleys. Here they soon root and are separated, and when the pots are well filled with roots, the plants are shifted into 6-inch ones, using a compost consisting of good loamy soil and manure. In cases in which pegging down the runners on the pots has been delayed too long, they are lifted and potted, and, if kept in a shady place for a short time, they soon make a potful of roots, but the plants thus raised are seldom so strong or good as runners prepared in the usual way. Pots containing Strawberries are placed on a level sheltered piece of ground, so that they may be well watered, and in October or November they are transferred to cold frames, in order that they may be protected from hard frosts. By the time when they require to be put into frames they ought to be pot-bound at the root, and their crowns and leaves should be well ripened, in order that they may start readily into growth, when required. All the care which they require in winter is protection from hard frost and heavy rains, and exposure during fine weather. When the stock of plants exceeds the amount of frame-room at command, a ridge of soil or ashes is raised out-of-doors, and into both sides of it the pots are inserted in a horizontal position; saturation with water, is, therefore, impossible, and when the crowns are dry the influence which frost exercises on them is less severe than would be the case if they were wet. Soon after the new year sets in forcing is commenced, and for the first batch, plants with strong well matured crowns are selected, and are started in gentle hotbeds in which they are kept near the glass. An atmospheric night temperature of 45° , with a rise of some 10° by day is sufficient at first, as the slower Strawberries are started and grown until they show flower the more likely are they to set well. When practicable, a little ventilation is given daily, particularly when the plants are in bloom; and, as soon as the fruit is set, the heat is gradually increased some 10° or 15° ; and, if ventilation can also be given at the same time, so much the better, as it assists in increasing the flavour of the fruit. Water is somewhat cautiously applied until the young fruits are formed, when it is given more liberally, and then, too, is the time to assist the crop with weak liquid manure. Sunk pits are those most in use for forcing Strawberries; and, in most of them a line of 4-inch piping, which runs along within the front wall, maintains an equable temperature. Span-roofed and lean-to houses, heated by means of hot-water pipes, are also largely employed for this kind of forcing. Mr. Wilmot's Strawberry-house, at Isleworth, is one of the best houses of the kind which I have seen. It is 10 feet high, about the same in width at the bottom, and the span comes down to the ground. The staging inside consists of nine shelves, arranged like the steps of a stair, as regards proximity to one another, and they are placed quite close to the glass. The plants most advanced in growth are placed on the top shelf on the sunny side of the house, and to these the plants lower down, and on the shady side, form good successions. Mr. Kneivitt, another celebrated Isleworth grower, has only four stages in his Strawberry-houses, but in that case they are broad enough to hold two rows of plants. When the fruit begins to colour water is partially withheld, as are also stimulants of all kinds. The produce is picked for market and put into punnets every second day. After yielding their fruits, the plants are transferred for a time to a frame, from which, as soon as they have become well inured to the weather, they are planted out into an open quarter of the garden. Here those planted out early yield some good late fruits. F.

THE VINTAGE IN FRANCE.

THE vintage is stated to have opened splendidly throughout France with every prospect of a bountiful yield, in spite of the ravages caused by the Phylloxera and late spring frosts. In the Bordelais, whence come the grand red wines of Lafite, Latour, Margaux, and Haut-Brion, besides a score of others only a few degrees inferior in renown, the vintage for the most part has been accomplished during

favourable weather, after a succession of warm showers had swelled the Grapes; and as a consequence the yield from this region, which suffered severely from spring frosts and hailstones, will still be considerably beyond an average one. In Burgundy the vintage commenced as early as the middle of September at Chassagne, a locality with a warm precocious soil that yields wines of excellent quality, but in other districts it was deferred a week later. Of the finer growths of the Côte de Beaune, the quality of which promises well, the quantity will certainly equal that of an ordinary year; but as regards the commoner red wines, produced along the slopes and in the plains, the yield will scarcely amount to more than a quarter of an average one, although there will be no falling off of the wines known as *arrièrecôtes*. In Lower Burgundy, where the vintage opened the last week in September, the excessively dry weather which had prevailed for some time past, coupled with the damage done in the spring, led every one to expect a comparatively insignificant yield; fortunately, however, as in other districts, at the eleventh hour the vignerons were favoured with a succession of warm showers, which conduced to a far more satisfactory result than could have been anticipated. It is not generally known that a certain degree of warm moisture in the week immediately preceding the gathering of the Grapes contributes more towards a favourable yield than any number of days of uninterrupted sunshine. In the Maconnais the vintage may be considered an average one, both as regards quality and quantity, while in the Beaujolais the new wine is considerably superior to that of the three last years, although the yield is only equivalent to an average vintage. There is a large deficiency from the Vineyards on the slopes, but in those on the summits of the hills the yield is most abundant. In Saône-et-Loire—along the Côtes Chalonnaises—where the vintage opened in the middle of September, the Grapes had completely matured, and the yield of the finer wines is very satisfactory; whereas, the Vineyards of the plains having suffered severely from spring frosts, the produce this year is insignificant. In no viticultural province of France has the want of rain been more severely felt this year than in the Champagne, where, in spite of the excessive heat, the Grapes are somewhat deficient in sugar, a serious drawback in the case of sparkling wines. The Champagne vintage was originally fixed for the close of the first fortnight in September, but it was not until the 17th that the gathering of the Grapes effectively commenced in the well-known Vineyards of Ay and Bouzy, and it was still several days later before the vintagers were at work at Haut Villers, Cumieres, Epernay, Cramant, and Le Mesnil. The average yield this year in the Champagne will exhibit a certain falling off, being estimated, in spite of the density of the Vine plantations, at no more than from 250 to 300 gallons per acre. With respect to the South of France, the vintage of the Hérault, which rose last year to the unprecedented quantity of nearly 300,000,000 gallons, being nearly quadruple that of the whole of Germany, including the annexed provinces of Alsace and Lorraine, promises this year to be still more abundant, and, as regards the Department of the Gard, many growers commenced vintaging too early in the vicinity of Nîmes, and, as a consequence, their wines are deficient both in colour and quality. In the neighbourhood of Redessan, where they began about the middle of September, the wines are said to be of good quality, and, so far as the Vines which escaped the attacks of the Phylloxera are concerned, the yield will be an abundant one. The storms which ravaged the neighbouring regions appear to have spared this department, the Vineyards of which had the benefit of a succession of genial showers during the summer. In the environs of Narbonne—the land of wine and honey—three months ago everything promised an abundant yield, but the excessively dry weather and great heat had greatly damaged the Grapes by the time the vintage commenced. Fortunately, about a fortnight ago, a more humid temperature set in, and the considerable quantities of fruit remaining to be picked largely profited by it, the wines being pronounced both richer in colour and more spirituous than usual. Scarcely had the vintage commenced in Roussillon than it was interrupted by torrents of rain, which inspired the owners with well-grounded fears as to the extent and quality of the yield. Unfortunately, the deluge came too late for the Vines on the hills, and too soon for those in the plains, the fruit of which is becoming mouldy; and it is feared that the produce of this celebrated district, which furnishes England with so many thousand pipes of so-called “vintage port,” will be far below what was anticipated. In the Orleanais, where the finest white wine vinegar in the world is produced, the yield in certain localities has been most excellent, while in others it has been unusually small. In the Lot-et-Garonne, the vintage has been especially prolific. After the small growers had filled their cellars, at least a fourth of the Grapes remained to be gathered. The fruit is large and well-matured, and the wine, which on account of its abundance, is offered at 45 francs the hogshead, is said to be of capital quality. In the Gers, where

the vintage commenced about a fortnight ago, the fruit is reported not to be particularly ripe, some little of the rain which we have lately had in too great abundance being sorely needed there.

Apple Gathering.—Mr. G. R. Green, of Hudson State of New York, has invented an ingenious method of gathering Apples, and so preventing the mischief which is done to the crop by shaking the tree, and avoiding the long and tiresome process of hand-picking. His invention consists of a piece of cloth or canvas as large as the top of the tree for which it is to be used, having in the middle a hole large enough to enclose the trunk, a slit is then made from the hole to the edge of the cloth, and the sides hemmed and a row of eyelet-holes made. When the trunk of the tree is enclosed in the hole the slit is laced up. At each corner of the cloth smaller holes are made and through three of these stakes are inserted, which are firmly driven into the ground. The fourth corner is attached to a barrel or basket, this barrel being lower than the stakes the Apples drop into it by their own weight.

Gathering Pears.—A Pear is a very delicate fruit, not only in the handling, but otherwise in securing the crop. If picked too early, like all or most fruits, it will shrink, remain hard or tough, and almost tasteless. If permitted to remain on the tree till ripe, the light and warmth—in other words, the sun—will, the fruit being dead ripe, evaporate its aroma, thus lessening the flavour as well as the juiciness. This is less the case with the thick-skinned specimens. A bruised Pear will soon perish. It therefore wants careful hand-picking, and careful handling all the way through till it is sold or used. If kept in the light, and where warm, whether picked or on the tree, evaporation will go on, and decay be accelerated. Keep, therefore, in a dark, cool place, neither too damp nor too dry, and be sure that the air is not charged with any foreign odour, as the Pear readily absorbs such odour. It is this impurity of the air that so often makes the difference in the same sort. A perfectly pure air, with darkness and coolness to slowly ripen and develop quality without evaporating it, is what is wanted, especially in the more delicate kinds. It will pay richly to give this attention. As to the time of picking, there are signs to direct us. The change in the colour is one, but is only to be trusted in experienced hands. The most common sign, and a safe one, is the readiness of the fruit to part from its twig, which it will do by lifting the Pear.—*Cultivator*.

The Parsley-leaved Bramble.—This is such an inconvenient customer to handle, the stems being so thickly studded with sharp spines, that the best way, I think, is to let it alone, and allow it to ramble as it pleases; in fact, more fruit is got from it in this than in any other way. I saw quite a mound of it lately in a garden, laden with fruit down to the ground. Planted in this way, it could be employed to cover waste pieces of ground where nothing else would do. Of course, when planted permanently in this manner, it would be advisable in the first instance to throw some good soil in to assist it, and every year some of the stools might be cut down to make them throw strong canes, and so ensure good-sized berries. It will thrive long in the same situation. At Fisher Holmes & Co's Nursery, Sheffield, the old stock plants have not been distributed since first planted, a dozen years or more ago, and they still bear in an extraordinary manner. Upon the points of some of the shoots I counted the other day about eighty fruits of different stages of ripeness. Even the young plants propagated this season for sale are bearing profusely on the earlier shoots. The fruit begins to ripen in September, and the plants continue to afford abundant pickings till November, or later if the weather is not very severe. Coming in as it does after all the other small fruits are over, it is a valuable addition to our hardy fruits. Our plants, which were planted about one year ago, have scrambled over a large extent of ground, and promise to fruit abundantly next year.—J. S. W.

Blackbirds in the Fruit Garden.—Perhaps you will allow me to describe my experience with the birds in my fruit garden this year. The principle, and in fact almost the only, depredators, were the blackbirds. Cherries, Strawberries, Currants, &c., one naturally expects to be attacked, but Pears, Plums, and Mulberries, I have hitherto considered safe from birds. The Cherries went first. I had a large tree full of fruit, which was cleared before it was ripe. Strawberries, Currants, and Gooseberries, followed as a matter of course. One morning, however, I was surprised to see the blackbirds attacking a tree of Jargonel Pears some time before they were ripe, and every Pear was so effectually destroyed, that I did not get one. Damsons, Plums, and all the varieties of Pears—of which there are a good many—were destroyed as they approached maturity; and a Fig tree, of course, came in for its share. This has been going on all the summer; and now they have taken to the Mulberries. I have, whilst writing this, driven eight blackbirds out of the tree. No doubt, I shall

be told by the friends of the birds, either that I do not know a black-bird when I see it, or that I was mistaken in supposing the birds to be the offenders. As most of the fruit trees, however, are in sight from my window, I have watched them daily with a glass, and have no doubt as to the fact. It is not very easy, from the locality, to kill many of the birds with a gun. Next season, however, I intend to offer a reward for blackbird's nests, and hope by this means to keep them down. I have little doubt that more than half of the fruit in the garden—which is a large one—has been destroyed by the black-birds alone. The residents in this part of the country seem to take it as a matter of course; but I certainly have never seen the same sort of thing before.—E. B., *North Wales*. [That blackbirds eat fruit with avidity is, we believe, admitted on all hands. The usual course taken by their friends is not to deny their identity, but rather to palliate their offences, as is done by Yarrell in the following sentences: "The food of the blackbird varies considerably with the season. In the spring and early part of the summer it consists of the larvae of insects, with worms and snails, the shells of which are dexterously broken against a stone, to get at the soft body of the animal within. As the season advances, they exhibit their great partiality for fruit of various sorts; and their constant visits to the garden bring upon them the vengeance of the gardener, whose gun is ever ready at hand to repel or destroy the numerous invaders. When, however, the enormous number of insects and their larvae, with the abundance of slugs and snails, all injurious to vegetation, which are eaten by black-birds throughout a great portion of the year, are duly considered, it may fairly be doubted whether the value of the fruit is not counterbalanced by services performed."—Ed.]—*Field*.

Walnuts.—Although it is a fact well-known to the trade, many of the public may be surprised to hear that of the large quantities of Walnuts now to be seen for sale in all our leading thoroughfares, the bulk consists of Nuts of French and Dutch growth. Indeed, the present is undoubtedly one of the most prolific seasons for Walnuts that has ever been remembered on the Continent. The chief consignments come from France, Belgium, and Holland, and are received and distributed by means of three separate agencies. The largest parcels are disposed of in Pudding Lane and its vicinity, while some are landed and sold at the Dutch Market near St. Katherine's Wharf, and others find their way to the more aristocratic regions of Covent Garden. At each place there is generally a great concourse of buyers, principally of the costermonger class, who gain an honest livelihood by hawking the goods about the streets. When it is stated that thousands of packages of Walnuts have been imported and passed into consumption since the opening of the season, some idea may be formed of the activity that has characterised so slender an arm of commerce as that depending on Walnuts. Those to whom numbers, quantities, and prices possess a sort of charm, may be told that a sack or bag of Walnuts weighs about 50 kilos, which are equal to about 110 lbs. English avoirdupois; that one bag contains about 4,000 nuts, and can be bought of the importer at an average of 14s. per cwt., so that at the rate of sixteen a penny the enterprising costermonger gets a profit of 7s. per cwt., which represents his greatest earnings, as it takes him a whole day to "sell out" a single bag or barrow-load of Walnuts.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

The "Peach Nut": What is it?—Can anyone tell me what fruit is that described in the following extract from an Italian letter?—"Within the last few days our list of fruits has been increased by the Peach Nut, a fruit peach-shaped and flavoured, but with the skin of a Plum. It has the Pomegranate shades of red and yellow, and when thoroughly ripe is delicious."—J. H. G.

The Joe-o-sot Cherry.—This was raised by Dr. Kirtland of Cleveland, and sent to this country with many other seedlings, one of which, Governor Wood, has obtained a permanent place. The Joe-o-sot is a large brownish-black Cherry, rich and sweet, ripening about the middle of July. It is not, however, better than many other black Cherries.—F. RIVERS.

Best Vines for an Orchard-house.—I should be obliged for information as to the best Vines for planting in a roomy and excellent orchard-house, but without any heating apparatus.—LADY T. [The best Vines for a cold orchard-house are Black Hamburgh, Buckland Sweet Water, Madresfield Court, and Foster's White Seedling; if a Frontignan Grape is liked, the early Smyrna will do well.]—F. RIVERS.]

Covering for Vine Borders in Winter.—Kindly state in your next number what is the best covering for Vine borders.—BURY. [There is nothing better than wooden shutters. We have used coverings made of asphalt roofing nailed on a frame, and found it answer well. It is cheap, also, and we would prefer it either to zinc or canvas, which, we think, would prove rather expensive. Wooden shutters are, perhaps, best and cheapest in the long run.—T.]

Preparing Cuttings in Autumn.—Cuttings of the Currant, Gooseberry, and Grape are better if cut immediately on the fall of the leaf, plunged into moist sand two-thirds of their length, and placed in a cellar. If Nature is as propitious to others as she has been to us, the cuttings will be found in the spring with the granulations completed at the lower end, and the roots just ready to push; and, on being planted out, they grow off immediately, forming, during the season, well established plants.—H. W. BEECHER.

GARDENING IN SPAIN.

(IRRIGATION OF HUERTAS, JARDINES, AND ALAMEDAS.)

The drought of the past summer has taught us, even in rainy England, the value of water in husbandry and horticulture; but this dryness of the season, which is the exception in our own country, is the rule in some others, and in no country of Europe is it more so than in the south of Spain. There, where water does abound, the land is as the garden of Eden, but, without this fertilising element, it would be a barren desert. We speak of river-water, for well-water is, in most districts, so charged with "villainous saltpetre," that it proves as deadly to the thirsty plant as sea-water to the thirsty sailor; and during six months of the year no rain, beyond an occasional thunder-shower, must be expected. With water you can grow anything, without it nothing—if we except some plants of the Cactus tribe, such as the Prickly Pear, which seems to have the property of flourishing just where nothing else, not even a blade of Grass or Esparto, will grow. There are several districts in the south of Spain, whose produce is of great importance in the world's market, and which owe their vast productive power solely to an intricate system of irrigation. One of these, to which the Moors gave the name of *Al-Bastan*—the Garden—on account of its prodigious fertility, lies in a valley watered by the river Segura. It is about 5 leagues in length by 3 in breadth, and is known at the present day as the Huerta (*hortus*) of Murcia. The vegetation was originally confined to the banks of the river, but the ingenious and industrious Moors, by a contrivance called the *Contraparula*, made the whole district one which recalls the most florid passages of the "Song of Solomon." From some distance up the river they cut canals, leading through the length of the valley around Murcia, and re-joining the Segura some distance below the city. Out of these canals run a number of small water-courses, permeating every allotment in the Huerta; while, by means of a sluice, the occupiers of these can, at the hour, and for the time prescribed by the authorities, water their land, which usually bears four harvests in the year. This system of irrigation the Spaniards have adopted for their private and public gardens, but as regards their *huertas* and *vegas*, they have done little more than keep in repair the water-courses bequeathed to them by the Moors. As water is the life of vegetation, and, consequently, of man and beast also, to say nothing of it as a source of national wealth, it is literally meted out to the holders of allotments, so that no man may get more than his share. The power of this fertilising agent being such, that Moorish poets have described the waters of the Darro and Xenil, which irrigate the Vega of Granada, as "streams of liquid gold flowing between emerald banks." In order, therefore, to get the full benefit of this, the plants in a Spanish garden are, for the most part, grown in gutters, or holes, instead of on raised beds of earth as with us. The Murcians frequently tell the stranger that whatever will grow in South America will flourish in their Huerta, and during a long residence in their capital we had opportunities of seeing much that bears out this assertion. All the glory of Oriental and Occidental vegetation seems to be gathered there as if in a vast tropical garden. There grow the Palm, the Olive, the Fig, and the Pomegranate; the Almond tree flourishes, and in its branches the grasshopper (of scripture) is a burden; "the husks of which the swine did eat" hang like great Kidney-

Bean pods upon the Carrob tree, and the Shittim tree gives a pleasant shade by the way side. The Cypress and the Turpentine tree grow in the cemeteries, and tall Canes whisper by the waterbrooks. The Vine and the Calabash plant ramble over verandah and trellis, the Magnolia opens its large flowers, and the Passion-flower, taking the place of Ivy with us, hangs in long tresses down the garden wall. The Orange, the Lemon, and the Mulberry tree, stand about as thick as fruit trees in an English market-garden, while beneath them, in the summer, grow fields of Tomatoes, and, in the autumn, of red Pepper. Wherever there is a barren, unwatered spot, the clumsy Cactus (Prickly Pear) shows its yellow blossoms or its ruddy fruit.

One of the common uses of this Cactus is, jointly with the Aloe-like *Pitera*, to form an enclosure, or a hedge by the way side, as in the accompanying illustration, both of these being extremely troublesome plants to meddle with. The Cactus (shown on the left in the engraving) is defended with little clusters of sharp bearded spines, which after they have once entered the flesh cannot easily be got out, but rankle and often cause sores. Indeed the law has thought proper to take cognisance of this, and there is a penalty attached to the sending to market of Prickly Pears (*Higos chumbos*) as the fruit of this Cactus is called, without the

previous extraction of the little spines which are found upon them, as well as upon the leaves, showing at a short distance like spots placed at regular intervals. It is usual also for the vendors of these Prickly Pears to hold them in a cloth whilst preparing them for the eater, who stands at the stall, and swallows the sweet pulp, stones and all, as quickly as the Londoner will oysters; the use of the stones being to counteract the astringent nature of the pulp. The *Pitera* is shown on the right of the engraving. This plant has a stiff fleshy leaf of a glaucous colour, and is tipped with a hard spine, while shorter ones are found down the sides for a little distance. Though it seldom is found of any height (except as regards its blossom stems) it is a formidable obstacle to

A garden in Spain (the Alameda at Cordova).

encounter. Little plots of land, remote from the city, are often fenced in with this stubborn plant, whose cold-green leaf contrasts strongly with every other. When it blossoms the flower-stems rise to the height of from 20 to 30 feet, and look like gigantic candelabra. Some of the holdings in the Huerta are private gardens of the wealthier classes, and are often enclosed with fences of plaited cane, looking very Chinese. Most of the plots, however, are open, as with allotment gardens in England.

The system of irrigation applied to the Huerta, is carried out in the public gardens of Murcia, the Glorieta, and Carmen. Here are various plants indigenous and exotic, all planted in gutters or holes, which can be filled with water at the appointed time. A very fine South American Plantain grows in the Glorieta. The garden Del Carmen, is provided with seats, fountains, and a statue, to which, as it changes with the revolutions, it would be unsafe to give a name. Murcia is not, however, quite independent of rain, for if the dry season be unusually long, the Segura sinks too low (from exhaustion) to supply all the watercourses, and recourse is had to our Lady of the Holy Fountain at Algezares, about a league off. The image is brought forth (for a consideration), and long lines of rustics accompany it, bearing the tall green canes before-mentioned. With these from time to time they strike the image, and cry—"Water, water, O Mother of the Holy Foun-

tain!" The Huerta of Orihuela, however, from its being lower down the stream, does not suffer so much from drought, and a local proverb says—*Lluva ó no llueva, trigo en Orihuela*.

Whether it rain, or do not rain,
In Orihuela there's always grain.

To water the Huerta of Lorea (the key of the old kingdom of of Murcia) a reservoir is made by damming up the stream; an enormous dyke of yellowish stone being constructed across the whole width of the valley. From the reservoir water is doled out to the lands below. As in a weary land, shade is chiefly sought in the public promenades, scarcely any town is without its Alameda. These are often of great beauty, as will be seen from the accompanying view of the Alameda at Cordova with its fountain throwing up water in a grove of Palms, Cypress, and Acacia trees. The Palm tree was first planted here by the hand of Abdu-r-rhaman, as a memorial of his much-loved Damascus; and the identical tree is still pointed out to strangers, growing in the Court of Oranges in front of the large mosque. The roof of this building was formerly of

able to take a promenade in the Alameda, assemble at their *rejias*, iron-grated windows, looking like birds in a cage; or may be seen standing in their balconies, and talking to their friends and acquaintances as they pass by. The Spanish *senorita* is usually well skilled in the language of flowers, and expert in that of the fan which is able to convey much telegraphic information—open six folds and turned upwards, it would signify "6 a.m." if it were reversed, "6 p.m." and so on. An appointment would be asked for by holding the closed fan horizontally between the thumb and finger. The lover generally takes his station against a house on the opposite side of the narrow street and looks up towards the balcony of his *senorita*, and we have on one occasion, in Murcia, seen a "Wallflower" of this description damped in his ardour by mischievous systems of irrigation from a balcony above.

J. M. WOODWARD.

Singular Fossil Tree.—In the bottom of the main shaft of the Virginia City Coal Company, El Dorado, California, has been encountered the trunk of a large tree, 4 feet in diameter—a lone

American Aloe naturalised in Spain.

Alerce wood, and the tree which supplied it (introduced by the Moors), was once plentiful in the neighbourhood, but it is now extinct. When, after a lapse of a thousand years, the roof was taken down, the timber was still sound, and being sawn into planks was much sought after for guitars. At the present day the tree is found in the Berber Mountains, and by the people of that country is called Laris (the root of the word Larch). The lover of that which is beautiful in Nature will doubtless regret to hear that the Palm is decreasing in Spain, partly because the fruit is inferior to the Barbary Date, and partly because the tree is often injured for the sake of providing the bleached Palm-leaves, which are placed in front of Spanish houses in Holy week, as a protection throughout the year against lightning. To procure these, this beautiful tree is tied up at the top like a Cabbage, its health being injured for the sake of a fair complexion. Young ladies also, in Spain, generally suffer a bleaching process, from their being so much kept indoors and in darkened rooms; they are not allowed to walk out except in company with a married relative, or some other chaperon. Hence, in an evening, those who are not

relic of an ancient and extinct forest. Where cut through by the shaft of this old tree is found to be perfectly carbonised, turned into coal. Outside, the old log is completely crusted over with iron pyrites, many of which are so bright that the crystals shine like diamonds. These crystals also extend into the body of the log, filling what were once cracks or wind-shakes, and even forming clusters about what once was the heart of the tree. This relic of an old-time forest lies far below the two veins of coal the company are about to open.—*Iron*.

A new way with Students.—Speaking of the method of teaching at Penikese School, Professor Putman said:—"Text-books are not allowed. Our way was to give each student a specimen of fish and ask him or her to study that fish and tell the instructor what had been observed. Thus we developed their powers of observation upon the external character of the fish. After they had studied the fishes for about two days, they were called upon to state what they had seen. Then the anatomy of the specimen was gone into, and the students were led on step by step until they had secured a very firmly-founded idea of the structure of a vertebrate animal. Then we asked questions as to the character of vertebrates, and finally they began to be original investigators. We really demonstrated in a

practical way the subject, which is exciting so much attention now of co-education of the sexes. We found that the ladies of the school were as capable in every way of making careful dissections and rendering careful accounts of the work they had done as the gentlemen; and, in fact, four or five of the ladies became original investigators before any of the gentlemen. This showed conclusively that the ladies had the power of becoming original investigators in science if they only would give the application."

CHILDREN AND FLOWERS.

ONE day, a child came into my garden; he surrounded a space of about a foot square with sticks; then he gathered some Roses, and planted them, by sticking the stalks in the ground. He did the same by a very fine Pink. When I returned, I felt a sensation of impatience, and if the child had been there, it is probable that I should have scolded him severely; but he was gone, happily for him, because I should have frightened him, and happily for myself, because I should have certainly said many foolish things. Not seeing him, I reflected a little, and remembered two things. The first is, that I do exactly what this child has done. Before I had a garden of my own, I walked freely in the woods, on the banks of rivers, on the shores of the sea. One day I bought myself a large plot of ground, which I surrounded with stones in the form of a wall; and I planted in it trees and flowers brought from all sorts of soils. The child had liberty to walk in all my garden, to see and inhale all the flowers; he preferred enclosing a little square patch, and to stick in it two or three of these same flowers, exactly as I had done, only it cost him nothing but the time in which he did it, and I have spent much money. Then, when his garden was made, he left it, went to amuse himself with something else, and forgot it; whilst I, with this plot of ground, have purchased a thousand cares. Formerly, if the wind in its fury blew down a tree, that was a spectacle for me; to-day, it breaks one of my trees, and that is a fear beforehand, a regret and a loss afterwards. I like old ruined walls falling into dust, and creating retreats for the lizards; now-a-days, I feel a great inclination to have my wall repaired, some of the stones being detached. The second thing I recollected was, that I formerly did, when I was a child, exactly the same thing in the garden of another person, that this child did in mine. My brother and I were then quite little fellows, and we were sent in the morning to a sort of school, not, I suppose, that we might learn anything—not that we might be at school—but that we might not be at home; where, probably, we made more noise than was agreeable. The master of the school, or of the academy, I do not know which title he claimed for himself, was like others; he was an honest *restaurateur*, who made up for the butter he did not put into the soup of his pupils by instruction which he was supposed to impart to them. The plan of these houses, in which it is always announced that the heart and the mind of youth is formed, is always invariably established on this problem: to find a means of selling soup in the most advantageous way possible. The problem is resolved in the manner of the possessors of cafés, who propose one nearly analogous: viz. to find the means of selling for fifteen or twenty sous that which people would have better at home, and without inconvenience, for four or five sous. The cafés have the journals; the schoolmasters, those other publichouse keepers, have Latin. This worthy, who was named M. Roncin, was the largest man I ever saw; this was his only means of obtaining consideration. Madame Roncin presided in the kitchen, with the help of a female servant. The other cookery, the Latin, was carried on by two or three poor fellows, ill fed and ill paid. They must have cost the establishment much less than the butter would have cost that ought to have been added to the soup, if a cook of another kind had been in question. To tell the truth, it was the servant that was the real mistress of the house. M. Roncin was a sort of cipher; and Madame Roncin, who directed everything, never decided anything without consulting with Marianne before the stove. We being among the number of the smallest, were shut up during six hours of the day in what was called the French class. We passed the time in the best way we could; we made birds and boats with paper—we played odd or even with marbles. When the master caught us, he confiscated our marbles, threw away our birds and boats, and placed us on our knees in a corner of the room; then he made us learn and repeat by heart something which began in this manner: "Grammar is the art of speaking and writing correctly," &c., of which we comprehended nothing, and he very little. He was a poor, old, thin man, who went through it all with the most serious countenance imaginable. There were nearly two hours of the day consecrated to what was called recreation. During these two hours they let us loose in a large court, in which were three or four old trees that had stood out against both time and the school-boys. What joy, and what cries, and what a tumult! Now we used to run and jump—how happy we used to be! It happened

one day that one of us, I do not know which, took it into his head to make a garden; he dug up with his knife, in a corner, a square about the size of a table, he traced walks of 4 inches in width, put sand on his walks, and planted some small branches torn from the large trees in the flower beds, and also a stalk cut from a Gillyflower, which had blossomed of itself in the wall. Gardens became the fashion. Those who, like us, were day boys, that is to say, only came in the morning and went away at night, brought, every day, branches of cut flowers and seeds of all sorts. The flowers were faded by the end of an hour, and the seeds were forgotten and replaced by others a fortnight before they could have germinated. My brother and I went in the morning, with a little basket, in which were put the provisions for the day—slices of bread-and-butter and some fruit, destined for a meal while the other boys were at dinner. We were humiliated by the neighbourhood of a garden that quite eclipsed ours. The possessor of this garden had, as we had done in ours, sown some Peas. His were much handsomer than ours. Perhaps he had taken them up less frequently to see if they had germinated. One day we were inspired with the means of putting an end to our envy, and, at the same time, of awakening it in our comrades. My father had a neighbour; each possessed the half of a large garden, which was divided only by a walk. This neighbour had some magnificent Hyacinths, and was very proud of them. We took it into our heads to transfer these Hyacinths to our school-garden. In the evening I stole quietly from the house, and went straight to the bed of Hyacinths; I trembled a little, but I seized one by the stalk. I pulled it in order to break it, but the root followed the stalk. I did not want the root—there was nothing pretty in that, and I saw no use in it. Nevertheless, I deferred separating it till I could safely throw it away; but I had not the time. I took a second Hyacinth, then a third; I concealed them in the cellar. I went into the house again, and my brother, in his turn, attacked the Hyacinth bed. Nisus and Euryalus did not commit greater havoc among the Rutulians. When morning came, never had we been up so early, or so ready to go to school. We laid eight or ten roots at the bottom of our basket, and three or four, the flower-stalks of which we had gathered without the root; and then we placed our bread-and-butter at the top. These are but had recollections, you will say, my friend; and yet, I can assure you, that neither my brother nor I acquired from this boy's trick any propensity for stealing. The same thing happened to St. Augustine, who, when a child, was a thief, as we were, and relates the circumstance in his Confessions with a sort of witty, half-roguish contrition. "There was," says he "a Pear tree near our Vine loaded with fruit; one night, after having, as usual, rambled about the streets, we went, a troop of young rogues and I, to gather these Pears; which we did, and if we tasted one it was simply for the pleasure of doing what we were forbidden to do." I had not, as St. Augustine had, the consolation of being punished for my crime by the crime itself. If his Pears were not sweet, I must confess that the Hyacinths were beautiful. My punishment arrived late; it did not arrive until yesterday, but it did arrive. The Hyacinths were beautiful, and we enjoyed beforehand the admiration and envy they would create at playtime. We went straight to school, under the care of the gardener, without stopping, as usual, to gaze into the shop windows. When arrived, as we knew the Hyacinths would stand a chance of being stolen, we would not place our basket in the corner where the baskets were usually deposited; we kept ours, and concealed it under the form between our legs. It appeared to us that this interminable class would never be over, or the moment arrive at which we could go and plant our Hyacinths. All at once the door was opened, and Madame Roncin entered. She called us both in one of her blandest tones: "I am told you have got some beautiful flowers for your garden. Let me see them. Then we were like La Fontaine's raven; we took our basket and gave it up to the admiration of Madame Roncin. In the first place, Madame took out the slices of bread-and-butter and placed them on the table of old Father Poquet; then she took out the Hyacinths, one by one, and ranged them near the bread-and-butter. At this moment I raised my eyes and saw, close against the windows of the school-room door, two faces! two formidable faces! that of the owner of the Hyacinths, and that of the gardener, whom my father had sent to fetch us home to expiate our fault. I will not inflict upon you the detail of the reproaches we received, or of the punishment reserved for us till our return to school the next day. We were ordered to carry our basket to the kitchen, where Madam Roncin and her servant were at breakfast. Both saluted us with the title of "little thieves." At first we cried a little; but my brother whispered, "I say, Stephen, did you see anything?" "Yes; didn't you?" And that which we had seen was, that on one of the stoves were two of the finest Hyacinths in pots, which Madame Roncin had contrived, by some means, to appropriate to herself. I soon forgot both the Hyacinths and our offence, but I could not help, yesterday, remembering both the one and the other. My beautiful Roses, that I had

looked forward to during ten months! my own diamonds! my dear flowers! I went every morning, from the day of their blooming, to salute them, the first thing on entering my garden; I examined them to see if anything had injured them, to see if any insect were gnawing the buds. I gazed at them, I breathed their perfume, and I felt myself rich and almost insolent. And this confounded child inhumanly tore them from their boughs, and stuck them in his garden, where they died in a few hours! And my Pink! a beautiful Flemish Pink, white with violet bands; a Pink which I had, only the evening before, obstinately refused to a lady who requested it of me! Then, and not till then, was I aware of all the grief I had caused our poor neighbour, the man of the *Hyacinths*. It appeared to me that I underwent one of those vengeance that Dido announces to the perjured *Æneas*:—

Exoriare aliquis nostris ex ossibus ultor.

That child was not then born who now forces from me such just reflections. In fact, it is our children who will repay us the pains and anxieties that we have cost our parents. At the same time, let us not require from them the tenderness we feel for them; it is not to us that they owe it or will pay it, it is to the children they will themselves have, and of whom they will complain unjustly, then, as we complain of them, and as our fathers complained of us. "We only remember the respect and gratitude we owe to our parents to require it of our children."—"Tour Round my Garden."

THE KITCHEN GARDEN.

NEW KINDS OF POTATOES AND THEIR CULTURE.

IN spite of sharp late spring frosts and a very dry summer, the Potato crop of the past season has been one of the best which we have had for several years—best, not in the sense of greater abundance, as the crop of last year was heavy, but as regards healthiness and an almost entire immunity from disease. Potatoes, in consequence, are now remarkably cheap, and cheap they will probably remain until after Christmas. One result of immunity from disease has been, that many kinds, perchance hitherto not well known, have exhibited their true characters, and we are thus in a position to give a fairer opinion of their merits than we have been able to do in previous years. My own Potatoes are in all respects truly excellent; and, where a selection of kinds has grown under special cultivation, in order to obtain good tubers for exhibition, the extra labour involved has been amply repaid; indeed, the longer I grow Potatoes the more I am convinced that no vegetable more thoroughly reaps extra cost and labour, producing, as it does, not only a heavier crop, but also one, in every way, of finer quality. Ordinary cultivation may be described as digging, drilling, or dibbling the tubers into the ground in rows, 2 feet apart, afterwards cleaning and earthing up in the usual way. Extraordinary cultivation consists in trenching and manuring in the autumn of the previous year; then, after the ground has laid for a few weeks, marking it out for ridges, 3 or 4 feet apart, as the case may be, and digging it a second time; each width so marked off is thrown into a ridge, and in this state is allowed to remain during severe weather. Whilst the soil is being thus purified by frost, a mixture of short rotten manure, vegetable refuse, or leaf mould, mixed with roadside parings and other matters of that kind, is frequently turned, well mixed together, and worked into a thoroughly pulverised state. This is then spread as thickly as can be spared along each furrow and well forked in, the same operation being repeated if the ground is at all stiff and heavy; then just before planting, a mixture of one-half slaked lime, and the other half equal parts of soot, guano, and salt, should be prepared, and if a quantity of fine wood ashes can be added, so much the better. This mixture is then strewn thickly along the furrows, and pointed in to the depth of 4 or 5 inches. The soil is then ready for planting. This is effected by having a drill drawn with a hoe down the centre of the furrow, and in this the sets are laid about 15 inches apart, and several inches of the finest soil are forked over them. Thus the ground remains until the haulm is well through it, when the ridges are again forked over, and thoroughly pulverised, a portion of the loose soil being placed around the young growth. In a fortnight a partial earthing up with a fork follows, and a final one is given a week or so later,

when beyond keeping the ground clear of weeds, little else is done until the period for lifting the crop comes round. Not the least important part of my mode of cultivation consists in the proper preparation of the sets. As a rule, the best seed-tubers are those of good medium size, clean, firm, and well-seasoned, and which have been stored through the winter in such a manner that, at planting time, the shoots made are stout and vigorous, and in no way drawn or blanched. Then, it is advisable, if extra fine samples be desired, to gouge out with a sharp knife all but the single crown eye, and it will be found that when the crop is lifted, there will be very few small tubers, and a very fine sample of large ones. Our most successful exhibitors all adopt this practice with the most satisfactory results, and I recommend this mode of culture and treatment of the seed-sets to all who may be disposed to enter fully into the matter of profitable Potato cultivation.

As to varieties, the following is a selection of sorts not commonly known, either because they grow only in certain districts, or because they are yet comparatively new. I will begin with an undoubtedly new kind, that has been this year grown only at Chiswick, having been sent there direct from Messrs. Bliss & Sons, of New York. It is called the New Early White, a designation under which it has been awarded a first-class certificate. The tubers are white, flattish-round in shape, of neat appearance, and produced in abundance; the haulm is dwarf and compact, and ripens off early. The special merits of this variety consist in its being a first early, a good cropper, and of excellent table quality. Veitch's Early Perfection is a first early, producing round tubers, white, smooth, and handsome; it is a fair cropper and of excellent quality; haulm, short, ripening off early. Fenn's Early Market is also a first early; tubers, round, large, and handsome; the skin is white, but the flesh is yellow and first-rate, both as regards quality and flavour; haulm, short and distinct. It is a capital cropper, and has received a first-class certificate at Chiswick. Both of these kinds are eminently garden Potatoes, and should be grown in rich soil. Fenn's Early White Kidney has also obtained a first-class certificate. It is a first early kidney, the tubers of which are white, handsome, and of good size; the flesh is white and of first-rate quality, and, in short, it is an improvement on the Ashleaf, which is one of its parents; the haulm is distinct and of moderate growth, and it is a good cropper. The Purple Ashleaf is a very old, but by no means a common, kind; it is not quite so early as the White Ashleaf, but it is a heavier cropper; its tubers are large and handsome, and the flesh is white and good. This is undoubtedly the best purple kidney in cultivation, either for table use or for exhibition. Wonderful Red Kidney is a variety that might well be termed the Red Ashleaf, although it differs materially from that kind, which is late in ripening, whilst Wonderful Red is a first early, producing handsome pale red tubers of good quality. Bountiful, a second early and a keeper, is another of Mr. Fenn's kinds, and has recently received a first-class certificate at Chiswick. The tubers have a moderately netted skin, deep red in colour, and exceedingly handsome; they are never unduly large, and are produced in great abundance; it is emphatically a bountiful cropper; it is one of the handsomest kinds for purposes of exhibition. During the past season an early second early white kidney has been grown at Chiswick, under the respective names of the Shiner, Sutton's Defiance, Cooling's Early Prolific, and others. It has an Ashleaf type of foliage; the tubers are large, flat, and handsome; and it is a good cropper; the table quality is not first-rate, but it may improve where grown in good soils. The glowing accounts given last winter as to the wonderful produce in America of the Extra Early Vermont, and its having received a first-class certificate at Chiswick, have caused it to be largely sold; notwithstanding the fact that the selling price was 2s. 6d. per lb. I am, however, compelled to say that it differs so slightly from the Early Rose that it is exceedingly difficult to discern the difference. It is, however, something in its favour, that although it produces a great abundance of tubers, few of them are so large as not to be of good table use. I shall grow it again another year before pronouncing finally on its merits. I have yet another of the Early Rose family, viz., Early Gem. This was sent us from America, and is an exact duplicate of the Extra Early Vermont. The best of all the Rose family, is the

Late American Rose, a very fine distinct kind with robust haulm, and, at least, a fortnight later in ripening than the others; its tubers are large, pale red, and slightly netted; the flesh is white and mealy. It is a very large cropper, handsome for exhibition, and a first-rate kind for a main crop. Another American kind, distinct and good, is Snowflake, which was selling last spring at 12s. per lb. Of course the stock is exceedingly limited, but as it is a large cropper it will rapidly increase. Snowflake resembles the better known Breese's Prolific in the haulm and shape of the tuber, but the latter instead of having a pink skin is of a brownish-white colour. The tubers are large, long, flat, and handsome, the flesh is very white and flakey, but it lacks flavour; still I consider it to be a valuable acquisition. Vermont Beauty also received a certificate at Chiswick last year, and is a first-class Potato; but this season it has exhibited a much stronger growth than last year, and has been later in ripening. The tubers are large, flattish-round in shape, and in colour the same as Flourball, but although a strong grower it ripens earlier than that kind, compared with which, too, it is a heavy cropper, and of much softer and better quality. It makes a fine exhibition variety. Last of the Americans is Compton's Surprise, a large late kind, having tubers, in colour much like those of the old Jersey Blue. The haulm is very robust, and needs plenty of space, and the produce is large. It is not a handsome kind, but will make a good field or cottager's main crop variety.

Turning now to some of our best home raised varieties, I will first allude to that very handsome round kind, the Rector of Woodstock, another of Mr. Fenn's seedlings that has been awarded a certificate at Chiswick. It ranks as a second early, and is a large cropper; the tubers are white, round, smooth, and very handsome, and of even table size. The flesh is of a yellowish white colour, and when well cooked it presents almost the perfection a table Potato, being mealy, soft, and of excellent flavour. It is also a capital exhibition kind. Model, is probably the best of Bell and Thorpe's seedlings, and is one of the handsomest of white round kinds; the haulm is tall, dark in colour, and rather late in ripening. The tubers are white, oval-round in shape, smooth and handsome, and good for exhibition. Of its table quality I cannot say much, but on dry soils it is fairly good. Webb's President is an old, but very excellent, second early variety, the haulm of which is rather dwarf and spreading; the tubers are very white, flattish-round in shape, and usually clear and handsome. It is first-class when cooked, and is altogether a most useful Potato. Blanchard, is a strong growing, round, white French variety, the tubers of which are large and handsome, the crown eyes being considerably splashed with purple. It is a good cropper, is of excellent quality, and makes a very distinct kind for exhibition purposes. Much like Blanchard, in the colouring of the tuber, is The Favourite, another of Mr. Fenn's kinds, but in shape it is more oval, and when cooked whiter, and more mealy. It is a good garden kind, the haulm being short. It is classed as a second early, and will well repay good cultivation. Waterloo Kidney is a distinct kind, the haulm of which is of medium height, and spreading. The tubers are large, white, and handsome, and of excellent quality. This is a capital variety for market, as the tubers are formed early, and are very white in colour. Perfection Kidney, is an early Lapstone and is the result of a graft of Yorkshire Hero into Fenn's Onward. It produces medium-sized and exceedingly handsome tubers, that are of first-rate quality. Excelsior Kidney is one of the finest forms of Daw's Matchless strain. It is a strong grower and does best in rather poor ground; the tubers are white, large, and very mealy when cooked. This kind also received a first-class certificate. New Cambridge Kidney is the result of a cross between the Fluke and Lapstone; it is a strong grower and a late ripener; the tubers are large, brownish-white in colour, and much netted; quality, excellent. Paterson's Improved Victoria is probably the best Potato Paterson has ever sent out, and is a first-rate kind for main crop; it is a strong grower and a heavy cropper. Of coloured round kinds the very best and handsomest purple is Scotch Blue, a dwarf-growing variety suitable for the garden; it is a second early and is a capital cropper; the tubers are pebble-shaped and handsome; flesh, white, and of excellent quality. Birmingham

Blue is a good pale purple skinned kind, and also a second early; the tubers are large, oval, and handsome; the flesh, white and of fine table quality. My last selection is Red Emperor, a kind now pretty well known on account of its extremely handsome tubers, which are usually pebble-shaped; flesh, white and of good quality. It is a heavy cropper and should be classed as a late second early kind. A. DEAN.

THE GARDENER'S FRIEND.

A CORRESPONDENT of the *Cultivator* has invented a useful little implement, which he has called "The Gardener's Friend." He says "It will make rows without a line, cross-check for planting Beans, Peas, &c., make holes for setting Beets, Cabbages, Onions, Strawberries, &c., any distance from 4 inches to 3 feet apart in the row, and will do it more easily, and in one-eighth of the time required by the old back-breaking plan. The instrument costs but little, and can be made in two hours by any person who can use a saw and axe. The following sketch shows its appearance. It consists of a wheel, made of boards, from 1½ to 3 feet in diameter, and 2 inches wide. The handles may be made of any desired length and pattern. On the edge of the wheel fix wooden pins 1 inch in diameter, wedge-shaped at the outer end, projecting 2½ inches from the rim. Bore holes 1½ inch deep and 4 inches apart around the wheel. In setting out Turnips, Onions, &c., leave all the pins in; for other plants, take out the pins as the distance apart requires. Operation: Decide on the distance you wish your rows apart, and stake off the distance at each end; wheel your Friend in position,

wheel across to the opposite stake, and you will have made a straight row, and the holes will all be made ready for the plants, in number from 50 to 1,000, according to length of rows, and all done in the time required to walk the distance."

The Drapers' Garden.—A draper states that the ground-rent of £15,000 per annum, which will be obtained by the Drapers' Company for their garden, is to be applied to the erection of a suitable building, in which to maintain and educate at least 300 girls and boys, children of poor clergymen, half-pay officers, and other professional men in indigent circumstances.

Ants in Dwelling Houses.—Several recipes for destroying ants have lately been given in the *Times*; Mr. Salter, of St. John's College, New Wandsworth, says:—Our kitchen was swarming in the summer time with ants, both winged and unwinged. Windows, tables, and floor were all covered with them. Observation told me that they came almost without exception from holes in the hearth, the heat being doubtless favourable to their generation. Objecting to being thus overcrowded with lodgers I did not want, I carefully poured some strong vitriol (sulphuric acid) down each of the holes, at the same time killing those who happened not to be at home. The dose must have proved fatal not only to the living, but also to all their eggs, for not an ant has since been visible indoors. Another correspondent recommends placing a saucer of weak rum and water, well-sweetened with coarse brown sugar, in any place frequented by the ants; into this, he says, they will flock by hundreds, and thus, to some extent at least, be destroyed. Any chink or aperture in the wood-work of the house, or of any cupboard or sideboard whence the ants are found to issue, may also be well peppered with advantage. Some years ago, says a third correspondent, at my house in the country a colony of ants established themselves under the kitchen flooring. Not knowing the exact locality of the nest, I endeavoured to destroy the insects with treacle, sugar, arsenic, &c.; but, although I slew numbers thus, the plague still increased. At last, bethinking myself that ants dislike the smell of tar, I procured some carbolic acid, and diluting it with about a dozen times its weight of water, I squirted a pint of the mixture through the air-bricks under the flooring, and my enemies vanished that day, never to return. It has always been successful. For crickets, &c., also, a little of this sent into their holes acts as an immediate notice to quit. Camphor placed wherever table linen is kept, is also said to drive away ants.

THE ARBORETUM.

ON PLANTING ON PEAT BOG.

By JOHN BLAIKIE WEBSTER.

THE planting of bog land not only claims the attention of the planter on account of the vast area which it represents both in Great Britain and Ireland, but also on account of the ever increasing demand for timber trees of home growth. Moreover, by reclaiming these boggy swamps, they would not only prove a source of revenue to the owners, but also have a beneficial effect in embellishing and improving the climate of the country. The present report refers to three plantations, or rather that portion of each plantation which is composed of deep peat or bog, and is situated in county Armagh, Ireland. The descriptive particulars of the bog previous to being drained and planted, are as follows:—The bog is about 60 feet above sea level, quite open and exposed to the weather from all quarters. It consists of deep, rank, fibrous peat, light brown in colour, formed by the remains of bog plants in an imperfect state of decomposition, caused by the excess of stagnant water which it contained, the whole pores being completely shut up, thereby excluding the action of the air, and rendering it cold, water logged, soft and shaking, and quite incapable of acting as the food of trees. It contains about 95 per cent. of combustible matter, and 5 per cent. of mineral matter or ash. No. 1 is a mixed Fir plantation, composed principally of Scotch Pine and Larch; that portion which consists of deep bog comprises an area of about 7 acres, and was planted in March and April, 1861. The principal arterial drain or main outlet is 33 feet wide at the surface of the ground, and the average depth from 8 to 10 feet, and the banks cut with a slope of 45°. It runs along the south-west side of the bog, and joins the Black water near Verner's Bridge, and falls into Lough Neagh, at Maghary. Commencing at the main outlet, the sub-mains were cut 8 feet wide at top, 2 feet at bottom, and 5 feet deep. At first an open channel was cut to allow the surface-water to run off; the drains were then gradually deepened to the required dimensions as the bog got dry and firm. These drains, as well as the principal arterial outlet, were cut several years before the smaller ones. The small drains were cut 3½ feet wide at top, 3 feet deep, and 18 inches wide at bottom, the distance apart varying according to circumstances from 12 to 24 feet. The whole of the peat brought to the surface in the course of excavating the drains was levelled out on the surface of the bog, and allowed to lie and drip, for one year before planting operations were commenced.

Claying and Planting.—In December, 1860, and January, 1861, the clay was brought and laid on the surface of the bog by means of a railway, capable of being wrought by manual labour. The rails are made in sections of 11 feet in length, and capable of being lifted and laid by a couple of men, one at each end. Then, by means of a turning-table, the waggons were directed to any point on the bog where the clay was wanted. The pits were then opened for the plants at a distance of 3½ feet apart, and in size from 12 to 14 inches on the side of the square. A couple of ordinary shovelfuls of clay was then laid down at each pit, and allowed to lie exposed to the action of the frost until spring. This work was commenced in the beginning of March, and finished in the beginning of April, 1861. The plants used were two-year seedlings, one year transplanted native Scotch Pine, and two year seedlings, one year transplanted Larch, the former about 10 inches, and the latter about 20 inches high; at the rate of 3,556 plants per acre, and in the proportion of two-thirds Scotch Pine to one-third Larch, with the exception of 100 plants, *Abies nigra*, about 10 inches high, which were planted here and there principally along the margins. In performing the operation of planting, each man was provided with a boy, and bag to hold his plants. The man mixed the clay and bog with his spade, and put about one-half of the mixed stuff into the pit; the boy at the same time preparing the plant by holding it in an inverted position in his left hand, while he disentangles and spreads out the roots with his right, he then places the plant in the centre of the pit, keeping the strongest roots to the south-west (as our strongest gales of wind come from that quarter), he then holds the plant in a perpendicular position, while the man, with his spade, lifts the staff and places it on the roots of the plant, and tramps it firm with his foot. Any loose stuff which may remain he then gathers round the stem and gives it a second tramp, when the work of planting is finished. Owing to the softness of the bog, and the action of the wind upon the plants, moving them backwards and forwards, a good many of them got swayed to one side by the month of May. The plantation was then examined, and any plants that were blown over set up and trampled firm with the foot. In the beginning of June the plantation was examined a second time, and, with the exception of a few plants here and there that required a little tramping, all the others were established and making fine young growths. In bog-planting,

a matter of great importance, and one which ought never to be neglected, is that of keeping the plants in their proper position until such time as the roots get established in the ground. The present condition of the plantation is very satisfactory, the height of the trees, both Larch and Scotch Fir, average from 10 to 12 feet, and are in perfect health. The thinnings are generally sold to small farmers for fencing purposes, the Scotch Fir at 9d. and the Larch at 1s. per dozen. The average height of the *Abies nigra*, is 10 feet, present value 9d. per dozen. The relative progress and value of this portion of the plantation as compared with another portion planted at the same time, and from the same stock of plants, on clay loam, is as follows:—Average height of Scotch Fir, 12 feet; present value, 1s. per dozen; average height of Larch, 15 feet; present value, 1s. 6d. per dozen; average height of *Abies nigra*, 8 feet; present value 6d. per dozen. The chemical composition as well as the physical properties of the bog have now undergone a great change. The clay which was used at planting has not only added weight and firmness to the surface, but also added to its aluminia, assisted decomposition, and rendered the whole surface a rich fertile bed for the roots of the trees. The growth of the trees since the formation has taken up the superfluous moisture, thereby rendering the whole of the 3-foot drains quite dry, and with the exception of the principal arterial drain and sub-leaders, none of the others have required cleaning out for the last five years. The bog has sunk about 2 feet since the formation. No. 2 is a portion of a mixed Fir plantation situated in the immediate vicinity of No. 1. The descriptive particulars of the bog previous to being drained and planted are the same as No. 1, and need not be repeated. The pits were opened the same size, and the same quantity of clay allowed to each pit as for No. 1. It was planted in March and April, 1862. The plants used were two-year seedling Larch and Scotch Fir, one year transplanted in a local nursery formed for that purpose on an exposed situation on the edge of the bog, the former about 20 inches high, and the latter about 10 inches high, and at the rate of 3,556 plants per acre, with the exception of one dozen plants *Abies Douglasii*, and one dozen plants Austrian Pine, the former about 12 inches, and the latter about 10 inches high. The Larch and Scotch Fir were planted in the proportion of two-thirds of the latter and one-third of the former per acre. The Austrian Pines and *A. Douglasii* were planted here and there merely by way of trial. The mode of planting was the same as that described for No. 1, the only difference being that the plants were brought fresh from the nursery each day as they were wanted, and inserted in the ground before their roots got dry. This proved to be a decided advantage, especially in early life, to that of having to bring the plants a distance from the public nurseries in spring. The plants made a fine start immediately after planting, and have continued in a healthy, vigorous state ever since. At the present date the Larch and Scotch Fir average from 10 to 12 feet high, and the thinnings have been sold at the following prices, viz., Scotch Fir, 9d., and Larch 1s. per dozen. Their relative progress and value, as compared with trees of the same age and species growing on sandy loam are equal. The Austrian Pines have attained an average height of 8 feet 6 inches, their progress and value, as compared with trees of the same species growing on a thin sandy soil are equal; present value, 6d. per dozen. The average height of the *Abies Douglasii* is 12 feet; present value, 1s. per dozen. Average height of the same species growing on clay loam is 10 feet; present value, 9d. per dozen. The trees growing on bog are well furnished with lateral branches, and the foliage of a dark green rich colour, whereas the trees on clay loam are not so well furnished with side branches, and the foliage much thinner, and of a yellowish colour. The present condition of the bog is the same as described for No. 1, and need not be repeated here. No. 3 is a series of plantations in the shape of long narrow belts, and situated upon the same property as the former. They were planted between the years 1846 and 1849 inclusive, the oldest portion being now twenty-five, and the youngest twenty-two years old. The descriptive particulars of the bog previous to being drained and planted are the same as that described for No. 1.

Draining.—The belts were laid off 20 yards broad, and a drain cut along each side 8 feet wide at top, 2 feet at bottom, and 5 feet deep. The bog was then dug 14 inches deep, and formed into ridges 5 feet broad, a small drain being cut between the ridges 30 inches wide at top, 12 inches at bottom, and 2 feet deep; these were cut at right angles with the side drains, and consequently had an outlet at each end. The bog was then allowed to lie for one year before being planted; the pits were opened the same size, and the same quantity of clay allowed to each pit as described for No. 1. The trees were planted at the rate of 3,556 plants per acre, and in the following proportion:—one-half transplanted Scotch Fir, about 10 inches high; one-fourth transplanted Larch, about 20 inches high, and one fourth common Spruce (*Abies excelsa*), about 10 inches

waterdrops work like magic under these hot suns, and the barren, high. These were planted as a mixture generally over the ground, with the exception of one small portion of a belt, 400 yards long by 20 broad, which was planted entirely with Larch. The work of planting was executed and finished in a similar manner to that described for No. 1. The plantations have been repeatedly thinned, so that the existing crops consist of about 600 trees per acre. The average cubic content of Larch per tree, in a portion of the plantation last planted, and which is now twenty-two years old from the date of planting, is 2 feet, at 10d. per foot—1s. 8d. The average cubic content of Larch per tree, the same age as the former, growing upon clay loam, is 2 feet 4 inches, at 1s. per foot—2s. 4d. The average cubic content of Scotch Fir per tree, the same age, and growing along with the Larch on bog, is 2 feet 3 inches, at 5d. per foot—11½d. The average cubic content of Scotch Fir, the same age, growing on clay loam, per tree, is 2 feet 4 inches, at 6d. per foot—1s. 2d. The average cubic content of Spruce Fir, the same age as the former, on bog, per tree, is 2 feet 3 inches, at 5d. per foot—11½d. The average cubic contents of Spruce Fir, the same age as the former, growing on clay loam, per tree, is 2 feet, at 5d. per foot—10d. The difference in the rate of price per cubic foot is owing to the inferiority of timber grown on bog, it being much softer, and not so durable, as timber grown upon hard ground; so that mere bulk does not always represent the true value. The bog, since the formation, has sunk about 2 feet, and presents a hard firm surface; the trees have taken up the sap from the bottom, thereby rendering all the minor cross-drains perfectly dry. The whole of the trees in the mixed portion of the plantation are in perfect health—not the least trace of any disease has ever been observed in them. That portion of a belt already referred to, which was planted entirely with Larch, is now twenty-five years old. The results, however, in this case are widely different from that of the former. The trees have been repeatedly thinned to allow room for their proper development, and are well furnished with lateral branches nearly to the ground; yet the whole group has a stunted, weatherbeaten appearance; the tops, for the most part, are bent from the south-west by the force of the wind; the foliage is thin, and of a yellowish colour; the bark is hard, dry, and brittle, and full of cryptogamic growths; the shape of the trunk is what is generally termed by woodmen "Carrot-grown"—that is, large at the butt-end, and not carrying up its thickness in proportion to its height. None of the trees, however, have been effected with ulcers, *Coccus laricis*, ground-rot, or pumping. One-third of the trees perished when young, one-third are now worth 4s. per dozen, and one-third contain on an average 1 cubic foot per tree, which is worth 10d. The average cubic content of Larch, the same age as the former, growing on clay loam, per tree, is 2 feet 9 inches, at 1s. per foot—2s. 9d. The bog here was dug, drained, clayed, and planted in the same manner as that described for the other portions of the belts, so that the cause of failure cannot be attributed to anything in connection with the formation. The failure, however, may be accounted for in this way—first, want of shelter; and, second, the rank, fibrous bog was too cold and wet for the soft, tender roots of the Larch. Bog of this class, although thoroughly drained, yet by means of capillary attraction retains fully six times its own weight of water, and may be compared to a wet sponge. Trees, planted in such a situation, unless capable of taking up the superfluous moisture from below, are sure to perish; this the Larch is not capable of doing but to a small extent in comparison with some of the hardy evergreen tribe of trees, hence the cause of failure. The bog here has only sunk since the formation 1 foot; decay is making slow progress, and, with the exception of a few inches at the surface, it continues in a cold, raw, green state. The best plan in this case would be to stub up the whole trees, and replant the bog with a mixture of native Scotch Fir and Larch. As soon as the Scotch Firs get established, they not only afford shelter, but also collect and pump up the moisture from below, dispensing it in vapour through the air, thus accelerating decomposition, and rendering the bog capable of supplying the necessary food for the Larch.

Remarks.—First—In preparing bog for planting, it should always be drained and made ready at least twelve months before planting is commenced. The size and quantity of the drains must be regulated according to circumstances, and should be determined on the spot. As a general rule, however, the principal outlets should not be less than 5 feet deep. On exposed situations the drains near the margin of the plantation should be laid off in such a manner (if possible) that the dreaded blast shall not blow right across them, as the trees growing along the exposed sides of such drains have not sufficient room to extend their roots, and the consequence is, that in soft bog whole rows of such trees are often upset by the wind tearing up the side of the drain along with their roots, whereas, when the ends of the drains are kept to the blast this is prevented. It is, therefore, desirable that this should be kept in

view at the time of the formation. Second—Bog should not be planted in autumn or winter, as the cold and tannin which it contains destroys the roots before spring. The writer made several experiments by planting a number of Larch and Scotch Fir in the month of January, 1866, and found that 80 per cent. of the Larch and 50 per cent. of the Scotch Fir died. As a general rule, cold deep bog should never be planted sooner than March or April. The writer has practised this plan with perfect success for the last ten years, and has never found it necessary to beat up or replant any of the plantations so treated during that period. Third—Large plants are objectionable in bog planting, as, from the softness of the bog and the height of the plants, they are easily upset by the wind, and require too much labour and attention to keep them in an upright position; and, if this is neglected, the result is, that when the tree begins to grow, the leader naturally takes an upright direction, thus forming the stem into a semicircular shape, thereby rendering it comparatively worthless. Two-year seedling plants, one year transplanted, are the best; transplanting has the effect of giving a better and more fibrous root, as well as a stout, well-furnished stocky stem.—*Highland Society's Transactions.*

Azara microphylla.—One of the neatest of evergreen shrubs known, and one which will be most welcome in our gardens, as it is nearly or quite hardy in our climate, is the above named Azara. It has, in fact, stood out unharmed for the past five years, at Coombe Wood, where it is cultivated by Messrs. Veitch & Sons. The Azara microphylla is a native of Valdivia, where it is found at an elevation of 3,000 feet. It has received a first-class certificate from the Royal Horticultural Society, and is, undoubtedly, one of the best plants of the hardy class which has been introduced of late years. It is of shrubby habit, growing 8 or 10 feet high, with spreading or drooping branches, which have a peculiar fan-shaped mode of development, exactly adapting them for training against walls. The foliage is exceedingly neat, but dense, of a dark shining green, and a bluntly ovate figure, the margins being toothed. The flowers are inconspicuous, so that the beauty of the plant must be sought in its densely set glossy foliage. We know of no plant which could be more appropriately introduced to cover a wall, where a neat clothing is required, than this Azara, and there is little doubt, from the experience gained at Coombe Wood, that in such sheltered positions it would prove hardy in most parts of the country.—*Florist.*

A Portuguese Pine Forest.—The road northward from Leca lies through the vast Pine woods which form so broad a zone along the Portuguese seaboard. The Pine of Portugal, is as a rule, the fast-growing *Pinus maritima*, very like our own Scotch Fir, and quite as ugly a tree when young. In some places the more picturesque Stone Pine is found, but it is of slower growth, and notwithstanding the greater value of its timber and the use as food of its Filbert-like cone kernels, it is little cultivated. The commoner Pine grows rapidly in poor soil, and fine trees are often seen with their roots in mere sand. The Pine forest is in general monotonous and unpicturesque, for the trees are always cut before they reach the dignity of "two ton timber," and the side branches are lopped year after year to within a yard or two of the tree top. The traveller passes league after league of straight-stemmed Pine, and wearies for the sight of a green field or vineyard. The Pine forest, too, as in other countries, is silent and deserted: blackbirds, jays, and magpies are the only birds commonly seen or heard. Now and then a wood owl flits out of the shadow of an ivied tree, and the occasional tap of a woodpecker's beak, or his sudden laugh like cry, are sounds that a traveller feels to be a relief to the stillness. Human beings are rarely encountered, though the forest maintains its own peculiar population. Where the trees are rooted in anything but blowing sand, Gorse grows; and the cutting of it once in every three years affords some profit. Gorse in Portuguese farm economy is of great value, being used for the bedding of horned cattle, while the whole of the straw of the farm is used for their food; a system that has many obvious advantages, and others that are not so obvious. Every now and then, in the depth of the forest, a party of charcoal burners is met with, or of sawyers and carpenters, who encamp in the woods, fell and saw up the Pines, and make the boards upon the spot into doors, windows, and boxes, that are carried long distances for sale. If the forest is in the neighbourhood of towns, the fallen needles and cones are collected by women and children and carried in nets on dokey-back for sale as fuel. These are the purely forestal industries—the only human life connected with it—but this dreary desert of Pine wood has its oases. Wherever a brook crosses the forest the scene shifts immediately, and the watercourse is margined by narrow fields of Maize, Rye, and Wheat, or orchards of fruit trees reach on either side as far as the water can be made to flow. The stream itself is bordered with polished Oak and Chestnut trees, over which Vines are trained. The

dusty soil is turned by it into fertile meadow land. The silence of the forest is exchanged in an instant for a concert of woodlarks and nightingales, and the refreshing coolness of the water-laden air and the green shadow of deciduous trees are positively delicious to the traveller who has passed through the shadeless forest and breathed the dry, ever-sunned air, pungent with the peculiar odour which the Pines give out.—*New Quarterly Review*.

PYRUS TORRINGO.

This forms a bushy shrub with a somewhat pendulous habit. It bears rose-coloured flowers in profusion, which are succeeded by very small fruit that ripens in September and in the beginning of October. It is red when ripe, but quickly assumes a reddish-brown colour, and has a sharp sourish taste. This shrub was introduced into Europe from Japan, a country of which it is, probably, a native. It is

Pyrus Torringo.

increased by grafting it on any of the stocks usually employed for Apple trees, and it may also be raised from seeds.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Best Time to Prune Evergreens: W. E. S. The end of February or the beginning of March is the best time to prune common Laurels, Portugal Laurels, and all evergreens that are liable to suffer from severe frost in winter. Ivy may be clipped at the same time, or almost at any time.

Do Conifers Enjoy Manure? H. D. We do not believe Conifers require either manure or carefully chosen soil if the climate is well suited to them. But decayed farmyard manure may be used without danger and with benefit in poor soils. Subsequent top-dressings of thoroughly decayed manure will further benefit the trees.

Evergreens for Walls: S. H. You might try the following, which will clothe the wall in question for a considerable height:—*Crataegus Pyracantha*, *Azara microphylla*, *Berberis Darwini*, *B. stenophylla*, *Escallonia* in variety, *Lardizabala biterminalis*, *Ilex* in variety, *Ceanothus papillosus* and others, *Euonymus radicans*, *Ilex latifolia*, *Cotoneaster microphylla*, and *Magnolia grandiflora*.

The Dunkeld Larches.—The following note, copied from a board near the tree, refers to the largest of the two original Larches growing in the grounds of Dunkeld Palace, at the west end of the Cathedral:—“*Larix europæa*. From Tyrol. Planted in 1738, circumference in 1872, at 3 feet from the ground, 17 feet 2 inches. Height, 98 feet 10 inches; and contains 423 cubic feet of timber.” There are many other fine Larch trees in the grounds at Dunkeld, but all are much inferior to the two just alluded to.—M.

The Pepperidge Tree (*Nyssa sylvatica*).—This is a very fine tree in the autumn. If anyone doubts it, let him go over to Prospect Park, in Brooklyn, not far from the stone cottage, on the south side, and he will have an opportunity to review his opinion, and to wonder why it is that one of the most magnificent colour trees of the American forests is so little known or introduced into decorated grounds. It ranks among the very first in merit, and stands among the very last in use.—H. W. BRECHER. [The *Nyssa* is a hardy tree, somewhat over the middle size; the leaves turning to a brilliant crimson in autumn.]

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

Hardy Flowers, Alpine Plants, and the Wild Garden.

WHILE the late autumn flowering plants still gladden the eye and give interest to the herbaceous border, the great majority of its occupants have already had their summer growth levelled with the ground, or are in a condition for that operation. Now, it strikes me that a word or two, as to what may be considered by many a very simple process, will not be out of place. Be it remembered that Nature's mode of removing the haulm is a gradual one, viz., by the ordinary process of decay, extending, in most cases, through the entire winter months. Admitting at once that, where neatness and trimness is an essential point, it will not do to follow Nature's lead too closely; nevertheless, we may take a lesson from her, and that, too, with advantage. The lesson is this—never to cut down too close to the ground, but leave sufficient length of the old stems that they may readily be bent to one side. Such stems are almost invariably hollow towards the base, and not unfrequently constitute channels whereby decay, owing to the continued presence or accumulation of water therein, is conveyed beyond the ordinary stem into the very heart of the root-stock. From this cause alone many a valuable herbaceous plant has been lost; therefore, though not absolutely necessary in all cases, it is well to act up to it as a rule. Another bit of advice I would give, bearing on the same operation, is, that the knife used for the purpose should always have a sharp keen blade. I know the supposition generally prevalent is that any old knife will do, but such is not the case. In many of the better class of herbaceous plants, the buds, upon which depends next year's floral display, are densely arranged on a somewhat fleshy root stock immediately below the surface of the ground, nor is this root-stock always tough; hence, when a blunt knife is carelessly applied to the old decayed stem, the jerk intended to remove the decayed part is liable to break off the crown at the same time, and thus leave a blank in your border beauty for the next year. In the wild garden this operation should always be left to Nature herself; let there be no cutting down until a general clearance takes place in spring. In many of our coarse-growing vigorous plants there is a beauty, even in decay. The giant-fluted stems of some of our Umbelliferae are like monumental effigies of the past. I remember once seeing a striking engraving representing the important part which these plants play in the winter scenery of a Siberian forest, and the most fitting comparison I could draw was that they resembled the “valley of dry bones;” it may be a weird fancy on my part, one that, possibly, Gustave Doré would share in; but, nevertheless, it had a beauty—albeit that beauty was of the past—of death and decay.

Cremation in the Garden.—Naturally, where herbaceous plants are cultivated in quantity, the material thus cut away is considerable. What then is to be done with it? Here, without hesitation, we recommend “cremation,” for this especial reason, that, with the dead tops, very often quantities of seeds are removed, and if these be consigned, as they generally are, to the rubbish-heap, they do not perish, but yield a beautiful crop in whatever part of the garden such rubbish may be ultimately utilised. My own plan, and one from which experience shows that undoubted advantages are to be gained, is to reserve all the haulm from the herbaceous borders as a basis for starting a fire, say about the beginning of November; a few days will consume a large quantity of this refuse; but by a prior arrangement all the summer's weeds and border rakings may be deposited in close proximity to where the crematory process is to take place, and by gradually banking up the fire thus formed with this refuse, it may be retained sufficiently active for a month or six weeks, during which time it will have consumed a year's accumulation, and leave some tons of ash and burnt soil; the rough stones, of which there is sure to be a bountiful supply, may readily be separated by screening, and the residuum has a value of its own, whose use I will explain by-and-by. No seeds or insect eggs will survive such an ordeal as this, that is one important advantage gained, and in the dry burnt soil you have one of the most powerful disinfectants there is; that is a no less important second advantage, and on these, I think, the value of the process fully establishes itself.

Too Vigorous Growth.—Amongst herbaceous plants, some are of a rather too roving disposition, in fact, regular monopolists, given to poach on their neighbours territories; these must be kept within bounds, and how is this to be most effectually accomplished? The natural suggestion that comes uppermost to anyone, even to any ordinary gardener's mind, would be to chop round with the spade, so as to reduce a plant, say, a yard in the diameter of its underground development, to 1 foot in diameter. Yes, it appears very feasible, but remember in all such peripatetic plants, that the outer part of the circle represents the vigorous progeny. What then is to be

done? Select a vigorous tuft from the outer circumference, and then with one of Park's steel forks (the only implement that should have a free pass into an herbaceous border) fork out all the remainder, turn the old soil well over, adding, at the same time, a good dressing of manure, and re-plant your tuft where the original plant stood. The reason I mention this so early in the season is, that now, when the ground is dry, the operation may be performed in one half the time, and with double the efficacy; this remark applies especially to heavy soils, where, if this absolutely essential process be attempted in mid-winter, the limits of a plant you wish to curtail will only be found to have extended all the farther for the operation. Bulbs, such as the genera *Scilla*, *Muscari*, *Hyacinthus*—all spring or early summer bloomers—and even the *Lilies*, though impatient of frequent disturbance or removal, will gradually become weaker and ultimately die out, if not subjected to an occasional, say a triennial, overhaul. This ought to be done at once, before even the young roots are formed, for they are sure to receive damage in the operation, and the result in the spring will be but too plainly visible in the weakly short-lived blossoms they will produce; in fact, under ordinary circumstances, their re-planting ought to have been three weeks or a month earlier than this, but the uncommonly dry summer has held the majority of bulbous plants in an unusually quiescent condition; with the recent stimulating rains, however, no time is to be lost, as the newly acquired moisture will soon produce that root development that it is desirable to anticipate.

Alpine Plants.—In all rockeries, and amongst delicate Alpine plants, continuous war must be waged against weeds, such as *Sagina procumbens* and *Cardamine hirsuta*, as also, our common Chickweed; all of these increase at this season with great rapidity, and, what is more, are certain to produce perfect seeds until almost mid-winter, whereby not only is present damage done, but the guaranteed perpetuation of the mischief is provided for in the seeds deposited on the surface of the soil ready for early spring development; the removal of these, and, in fact, all weeds, requires continuous and careful supervision on the part of the successful cultivator. A like watchfulness is necessary as regards snails and slugs, whose appetites appear to increase in a compound ratio with the diminished vital activity of the plant, hence the seriousness of their depredations at this season of the year. The season is almost too far advanced for increasing herbaceous or Alpine plants by division, excepting, of course, such as the mossy *Saxifrages*; these do better now than earlier on, but cultivators must be careful, as a general rule, not to disturb the roots at this season; for, if they do, so surely will they meet with disappointment. The time for repairing damages and restoring root action, after the mutilation which must necessarily attend the process, is too limited; and a severe November frost will, at least in heavy soils, leave them on the surface of the ground. However much it may be against the grain of the cultivator, this operation must be performed either in August or, better still, in the beginning of April, when the renewed vigour of Nature is capable of repairing the most severe damages. In speaking of weeds, I omitted to mention the Lichen-like *Marchantia*, which in some places is a perfect pest, increasing, as it does, by spores developed in the little umbrella-like tops, by minute bulbils proceeding from the cup-like processes on their upper surface, and by fragmentary divisions. It not only covers over the entire surface of the soil, but smothers all the dwarf-growing plants. In the former case, it prevents the free and beneficial action of the air on the soil; in the latter, its action, though mechanical, is none the less objectionable. The best mode of checking its growth is to arrest its early development by constant watchfulness, by removing the soil wherever it appears; and if, in this process, the roots are bared, replace that removed by a surfacing of fresh soil, submitting the old to the crematory process before described, which alone will effectually destroy the various modes which Nature has provided for its increase.—J. C. NIVEN.

The Flower Garden.

The frequent falls of rain and the mild genial weather experienced during the month of September have rendered the flower garden more gay than it has been at any other period during the present season, any deficiency of bloom being amply compensated for by the increased brilliancy of the foliage of various sub-tropical plants, Tricolor-leaved *Pelargoniums*, and such plants as the *Coleus*, *Iresine*, *Alternanthera*, &c., together with such shining-leaved succulents as the *Echeveria metallica*, *E. secunda glauca*, *Sedums*, and *Sempervivums*; but it must, nevertheless, be borne in mind that the season is very considerably advanced, and that a degree of watchfulness is necessary as regards tender species of plants which it may be desired to preserve until another season; on that account, mats, or, what is better, pieces of frigid domo, should be held in readiness to cover up beds of such plants whenever danger is apprehended, until they can be lifted and potted, and placed under glass; and it is of great importance that this should

be done before they have been injured by frost. Young plants of the various sorts of variegated and Tricolor *Pelargoniums*, which have been bedded out during one season, will be found to make excellent stock for bedding out during the following summer; they should, therefore, be taken up and potted at once.

Preparing for Spring.—Wherever a system of spring bedding is contemplated, the arrangement of the flower garden should by this time be decided upon; and wherever *Hyacinths*, *Tulips*, and other bulbs, are intended to occupy any of the beds, such bulbs should be planted as soon as possible, but not before the beds have been duly prepared for their reception by being deeply dug, and by the introduction of a liberal dressing of well-rotted hot-bed manure or good leaf mould. This is absolutely necessary in cases where *Pelargoniums*, and other gross-feeding plants, will be found to have considerably exhausted the soil of the beds. The splendid effect which can be produced by a judicious arrangement of early-flowering *Tulips*, and other spring bulbs, is very remarkable, and should be seen in order to be duly appreciated. It is, nevertheless, inadvisable to plant the beds of the flower garden with bulbs alone; as, if this is done, it must necessarily leave the beds destitute of verdure for some considerable portion of the season; and where such beds are (as is frequently the case) seen from the mansion or residence, this is objectionable. But this may be readily obviated by carpeting or planting the surface of the beds with some of the many dwarf, hardy, early flowering, herbaceous plants, such as the *Aubrietia purpurea*, *græca*, and *Campbelli*. These are amongst the most effective and continuous bloomers of all spring flowering plants; also, *Alyssum saxatile*, *Arabis alpina*, *lucida*, *præcox*, and *purpurea*, *Bellis perennis*, *i.e.*, the various varieties of double *Daisies*, *Gentiana acaulis*, *Hepaticas* of sorts, *Iberis corifolia* and *sempervirens*, several early flowering varieties of the *Iris*, *Myosotis azorica* and *disitiflora*, spring-flowering *Phloxes* of various sorts, *Polyanthus*, double and single *Primroses*, *Saxifrages*, *Sedums*, *Sempervivums*, *Silenes*, *Tussilago Farfara* variegata, *Veronica alpina* and *incana*, *Vincas* of sorts, *Viola cornuta*, *cornuta alba*, *lutea*, *Mauve Queen*, and *Perfection*, together with double and single *Violets*, various kinds of bedding *Pansies*, double and single *Wallflowers*, &c. Beds, which may have been planted in the "carpet" style during the summer may, with some trifling alterations, be rendered nearly as attractive and interesting throughout the winter and spring months as they were in summer, by merely substituting suitable hardy species of plants for such tender sorts as cannot exist in the open air during winter, such as the *Alternanthera* and the *Coleus*; while, at the same time, many of the plants used for this purpose during summer are perfectly hardy, and may be allowed to retain their position undisturbed—such as the *Golden Feather Pyrethrum*, *Stellaria graminea aurea*, *Golden-margined Thyme*, *Sedums*, and *Sempervivums*. Even the *Echeveria secunda glauca*, so useful for this style of planting, although not altogether hardy, will nevertheless take little or no harm from an exposure in the open air during a somewhat mild winter, and suffers generally more from damp than cold.—P. GRIEVE, *Culford, Bury St. Edmunds*.

Trees and Shrubs.

The present is a very suitable time to plant trees and shrubs of all sorts. The soil is now in a moist and favourable condition, and the plants have ample time to become somewhat established in the soil before very severe weather is likely to set in. In planting ornamental Coniferous trees upon lawns and elsewhere, it is of the utmost importance to make a judicious selection of sorts, having due reference to the character of the soil, as well as to the effect which it may be desired to produce; and, in the distribution of the various species, the habit of growth, and the appearance which each plant will be likely to present in the course of a few years, should be taken into consideration. As lawn trees, the various species of *Picea* are unsurpassed, and conspicuous among them is *Nobilis*, with the rich glaucous bloom which covers its young shoots, and the dark or blue-green shade of its older leaves; also *Nordmanniana*, with its fine habit of rapid growth; while there can be few more handsome lawn trees than a well developed specimen of the *Douglas Fir*, or *Picea Douglasii*. But this beautiful tree is seldom found to succeed well on a very light or poor gravelly soil; while *Picea Pinsapo* with its fine dark green foliage, appears to make itself at home in almost all sorts of soils. *Abies Albertiana*, is also a valuable ornamental tree, and bears a considerable resemblance to the *Hemlock Spruce*, or *Abies canadensis*, and generally succeeds well in either a light or heavy soil, while the latter species cannot be induced to grow in a light dry soil. The *Wellingtonia gigantea* is also a most useful lawn tree and should be extensively planted, it succeeds well in all kinds of soil; as does, generally, the beautiful *Cupressus Lawsoniana*. Considerable diversity of habit and general appearance exists, however, among seedling plants of this species, and the best habited plants should,

consequently, be selected for the most prominent positions. Amongst hardy trees and shrubs, with variegated and coloured foliage, the variegated form of the *Wellingtonia gigantea* is well worthy of attention; as is also the *Thuopsis dolabrata variegata*, which is equally hardy as its green-leaved congener, and the beautiful gold-striped Yew, or *Taxus baccata aurea variegata*, and its improved variety *Elvastonensis aurea*, by far the brightest of all the gold or silver-striped sorts, more particularly during the winter months, when it is hardly surpassed by the more symmetrically habited *Taxus baccata Barroni femina*, the most free-growing of all the golden-striped Yews. The *Taxus fastigiata variegata* is the exact type of the well-known Irish Yew with golden-striped foliage; and when these plants, and many others, have become better known and are more extensively used, they are calculated to give a charm to the landscape, or at least to the grounds surrounding country residences, which can hardly at present be contemplated. In addition to the various species of ornamental and variegated plants which have been already alluded to, mention may be made of some of the many varieties of the beautiful Japan Cypress or *Retinospora*. *Retinospora pisifera aurea* is a golden variegated plant of great beauty, and forms a lovely object upon the lawn, where it contrasts agreeably with dark-foliaged plants of various sorts. So exceedingly graceful is the fine feathery foliage of this plant, that it is considered by some as one of the most beautiful of the many recent introductions from Japan. A writer in *THE GARDEN* of last week (see p. 320), recommends the substitution of this plant for Box as garden edgings, &c., and has proved its adaptability to that purpose, finding it to be perfectly hardy, and bearing clipping with impunity. When it becomes sufficiently plentiful (which is perhaps already the case) to be used for this purpose, its very pretty appearance will doubtless cause it to be preferred to Box, or to most other plants for forming marginal lines to shrubbery borders, &c., and to be used in various ways in connection with dressed grounds. *Retinospora ericoides* is also a very pretty shrub, and its leaves in winter become of a violet or reddish colour, which renders it very ornamental. There are also many varieties of the gold and silver variegated Hollies, which ought to be extensively introduced into the pleasure grounds, producing as they do, a truly grand effect in winter, and lighting up the landscape as if by magic; while associated with them may be *Aucubas*, of various kinds, and the pretty Japan Spindle tree, *Enonymus japonicus aureus variegatus*, and *latifolius albus variegatus*, &c. A judicious selection of such trees and shrubs as has just been mentioned, together with many others of equal value, as ornamental plants, skilfully handled, will go far to render the surroundings of a country residence nearly as attractive and beautiful in winter as in summer.—P. GRIEVE.

Annuals for Autumn Sowing.

No time should now be lost in getting these sown. A light soil, not over rich, suits them best. When the plants are up they should be thinned, so that every plant may stand clear of its neighbour. The great enemy of autumn-sown annuals is damp; but, by sowing in light soil in an open spot, and thinning well, they will be more hardy than they otherwise would be, and better able to withstand damp and frost. If they are to be transplanted into beds or borders in the autumn they may, in that case, be allowed to stand more thickly in the seed-beds. The best plan to deal with slugs, which sometimes injure autumn-sown annuals, is to look over the beds, night and morning, and to destroy as many as possible. By laying Lettuce or Cabbage leaves among the beds, and looking them over every morning, slugs may be kept from doing much damage. The following is a short list of kinds most suitable for sowing every autumn, viz.:

—*Alyssum maritimum*, white, sweet-scented, $\frac{3}{4}$ foot; *Bartonia aurea*, bright yellow, $1\frac{1}{2}$ feet, tender; *Calliopsis*, yellow spotted, 1 foot; *Candytuft*, purple and white, lilac; *Clarkia pulchella* and *alba*, rose and white, $1\frac{1}{2}$ feet; *Collinsia bicolor*, purple and white, 1 foot; *C. grandiflora*, blue and purple, 1 foot; *C. verna*, blue and white, 1 foot; *Erysimum Peroffskianum*, orange, $1\frac{1}{2}$ feet; *Eschscholtzia californica*, yellow, 1 foot; *Eutoca viscidula*, dark blue, 1 foot; *Gilia tricolor*, white lilac and purple, $1\frac{1}{2}$ feet; *Leptosiphon densiflorus*, lilac and white, 1 foot; *Limnantes Douglasii*, white and yellow, $\frac{1}{2}$ foot; *Lupinus nanus*, blue and white, 1 foot; *Malope trifida grandiflora*, crimson, $1\frac{1}{2}$ foot; *Nemophila insignis*, blue, $\frac{1}{2}$ foot; *Saponaria calabrica*, bright pink, $\frac{3}{4}$ foot; *Silene pendula*, pink, 1 foot; *S. ruberrima*, carmine-rose, $\frac{1}{2}$ foot; *Virginia Stock*, red and white, $\frac{3}{4}$ foot; *Venus's Looking-glass* (*Specularia perfoliata*), blue, lilac, and white, $\frac{3}{4}$ foot. Sweet Peas may be sown at the end of this month or the beginning of November, and by selecting a sheltered border and staking them as soon as they are 2 or 3 inches high, they will commence flowering early in spring. This is one of our most useful plants for supplying cut flowers, but it is seldom that one sees it grown during winter. It is, however, perfectly hardy, and may be sown now as well as in spring.—Q.

Indoor Fruit Department.

A good holding deep loam, fresh from an old pasture, is acknowledged to be the best material for Peach trees; and, indeed, for almost all sorts of fruits. It may be dug up and carted into the borders at once, without any storing. After long experience of a soil whose basis is clay, I have found that it maintains the vigour of the trees for a long period of years, with an annual top-dressing of cow-dung, and the occasional removal of a few inches of effete soil immediately on the surface of the border, and substituting fresh loam. Now is a good time to renovate Peach-tree borders; well ripened Peach trees may be entirely lifted out of the borders, and new borders made with the material just indicated, taking the precaution of seeing to the drainage, and making the soil compact as the border is being filled up. The roots should be spread out carefully on some of the finest of the soil, again covering with more of the same material; well treading the whole down, and finally giving a good watering. Trees planted in this way may be forced with the certainty of success, provided they have had their wood thoroughly ripened. The weather continues, on the whole, favourable to the ripening of Melons, but they must now be assisted with a little fire-heat, if possible; fruit in cold unheated pits will have a struggle to finish well; all sun-heat must be husbanded, short of actually burning the plants, and the fruit must be elevated on flower pots. Improved Victory of Bath and Colston Bassett are good sorts late in the season, and we should not like to be without the old Golden Perfection; Little Heath, notwithstanding its bad name, is one of the very best for late work, as it positively does best with rather cool treatment. All Strawberry plants had better now be placed in cold pits, in order that their roots may be protected from cold rains and frost; if all cannot be stored in pits, at least those required for very early forcing should have the benefit of this protection, and see that the drainage of the rest is thoroughly clear; if not standing on boards they should occupy a high and dry position on ashes or gravel; if much cold rain should ensue, the pots may be turned over on their sides for a time. There is no better Strawberry for very early forcing than the old Black Prince in small pots. Cucumbers may yet be planted for winter; indeed, layers may be taken yet from old plants, pegging a good-sized branch, with three or four leaves on it, into a 48-sized pot. In a week such layers will be fit to sever and plant out. If a pit has been got ready for their reception, they will grow and fruit at once. A bottom-heat of about 75° will be sufficient, the moist autumn weather which we are experiencing being altogether favourable for Cucumber growing. The temptation to over-crop must, however, at present be resisted, or failure may come at Christmas and afterwards.—W. D., *Canford*.

Vines and Pines.

Late Vineries need now but little attention. Lady Downes, Alicante, and one or two others, which retain their foliage fresh and green until far on in the season, should have such leaves as are in contact with the fruit removed, as they collect and retain damp about the berries, an evil now to be guarded against. A free circulation of dry air, which can only be obtained by having a clear space about the bunches, is what is required. However unnatural this clearing off part of the foliage may appear to be, no injury seems to result from it. See that former directions as regards Vines and Vineries for early starting are attended to. If the roots of Vines intended for starting about the beginning of November are chiefly outside, a heap of fermenting material should be placed on the border, spreading it out as far as the main feeders are supposed to extend. Leaves and litter are the best material for this purpose, and the bed or covering should be about 3 feet in thickness. A covering of boards, glass-sashes, or some such protection, placed on the top of all, keeps damp and cold out, and the bed thus protected retains the heat much longer than it otherwise would do. If forcing is to be commenced about the first of next month, it is best to put this covering on a week or two before that time, in order that the roots may feel the influence of the heat by the time when they are required to start into activity. Be it remembered, however, that fermenting material is but a poor substitute for hot-water pipes. The system of having Vine borders heated with hot-water pipes is the best as far as early Grape-growing is concerned. The hot-water pipes should be laid in a chamber resting on the concrete at the bottom of the border; with these, valves should be connected, so that the heat may be regulated as desired. The application of heat in this way is certain, but it should never be used longer than is absolutely necessary. Some prefer having all the roots of early Vines inside the house, but, when thus confined, they soon become exhausted, and the fruit on such Vines is never, at any time, so good as on those with roots unrestricted. As regards Pines, these should now receive a general shift. The plunging material will, doubtless, have fallen away considerably since young plants were put into it early in

summer. It is not advisable to touch beds, containing Queens, for early starting at present. When they are about to be started is the time to stir them up, and to give the plants, if necessary, a little more room, but, beds in which Smooth Cayennes, Jannicas, and similar kinds are growing, should be renovated. Collect all those showing fruit, and, if possible, give them a small house or pit to themselves, as they require to be kept a little hotter and damper than non-fruiters. Where a compartment cannot be spared, place them at the hot end of the house. Keep such plants as have not started altogether, and to these add a good portion of fresh fermenting material, as a bottom-heat of 85 or 90° will start many of the full grown ones into fruit immediately, and this fruit will come in nicely before the early Queens. Take the opportunity of washing the glass and wood-work when the beds are cleared, so that everything may be clean and trim throughout the winter.—J. MUIR, *Chesham*.

Hardy Fruit.

There is no better month in the whole year for the making and renovating of fruit-tree borders than October. Early in the month, and if possible before much rain falls, all exhausted worn out trees should be destroyed, root and branch, if past recovery; the soil should be removed bodily to a depth of 2 feet, and new borders made. If the trees are capable of renovation, there are two general methods of proceeding. One is to take the tree up entirely, cutting away all decayed or useless roots, and carefully preserving all sound and useful ones. Let these be bound round with a wet mat, or some other good non-conductor to keep the roots from the light and air. Then proceed to remove all exhausted soil to a depth of 24 or 30 inches, and substitute maiden loam, sweet and fibry—just such as you would prefer for pot plants, only heavier; for fruit trees like a loam somewhat adhesive, and what cultivators term clayey. That, with skilful top and bottom management, is the soil to yield fine Peaches, Nectarines, Plums, Apricots, and Pears. Spread the roots through this in a horizontal direction, flood them in, and should dry weather prevail, check evaporation from the wood and dying leaves, by frequent overhead sprinklings, and the roots will start at once and get a safe foothold of the new ground before winter. There still remains a middle course for the renovation of exhausted trees—neither a new border nor uprooting, but something between the two, managed thus—proceed to remove all the exhausted soil possible, and also all weakly diseased roots, without, however, disturbing more than is inevitable either of good soil or sound roots. Then fill up and in among the roots with maiden loam as before, starting all the fresh roots to the best advantage in the fresh soil. Sometimes the effect of this course is the sudden conversion of worthless trees into models of health and fertility. There is less risk than in transplantation, and less loss of time than in renewals. The skilful practitioner can tell at a glance after inspecting the top, and more narrowly scanning the bottom, whether a tree is likely to recruit its energies or not by this partial renewal of its root-runs. As to the forming of new borders, these dry seasons compel us to examine the very foundations of our practice. As the result of such severe scrutiny, I have been forced to the conclusion that drought—not water—is the natural enemy of the fruit grower throughout a great portion of England, including the whole of the eastern counties; therefore, on the gravel, chalk, sand, and other mixed and porous sub-soils, drainage may safely be dispensed with. It is unnecessary, if not injurious, and the space that it occupies may be more profitably filled with porous loam. When the soil is too adhesive the mass of the border may be drained, that is, its whole texture may be rendered pervious to the passage of water by one-sixth of its whole bulk being composed of burnt clay, lime rubbish, or road sand. The drainage will thus be placed in the border, not under it, and in the border is the best place for it. Further, no fruit-tree borders must either be made or mended in wet weather.—D. T. FISH.

Kitchen Garden.

Every garden, however small, should have its warm specially-prepared border for bringing forward early vegetables and salads; the soil, if not naturally deep and rich, should be made so, and, as the space devoted to this purpose will be small in proportion to the rest of the garden, there should be no difficulty in doing this—I am assuming that all gardens are well drained, either naturally or artificially, and that, therefore, no stagnant water can remain in the soil to lower its temperature. A well-sheltered border, 50 or 60 yards long and 10 or 12 feet wide, with a deep, well-drained, thoroughly-enriched soil, will furnish a large amount of early produce. Such a border should, if possible, be raised above the natural level, with a considerable inclination to the south. For the purpose of shelter only, a good thick hedge is, in some respects, superior to a wall; but, where neither are available, a fence of reeds, that can be put up in a short time by any handy labourer at a trifling cost, will be found of very great advantage. If

the fence is adopted, and if it is of considerable length, the ends should be closed in, and one or more divisions, in proportion to its length, should be added for the purpose of breaking and distributing cold currents that always rush along the sides of any obstacle. In large gardens, where there are long straight stretches of wall, temporary screens, starting at right angles from the wall and extending the full width of the border, would be of very great advantage early in spring. In many gardens south-wall borders are used for early vegetables; and, where these are of considerable width, there can be little objection to a few feet along the front being lightly cropped. It is, however, at best, but a species of compromise requiring very careful management if the trees on the wall are to be kept in health. I am convinced that many Peach and Apricot trees have been ruined by this close cropping and digging, destroying their surface roots. It is probably true that few gardeners are so favourably situated as to be able to carry out, to the full, their ideas in this respect; but I am certain that the less wall borders are cropped the better it will be for the wall trees, unless, as I have just observed, the borders are wide—say, from 12 to 15 feet wide; then, of course, the trees and vegetables might divide the border between them, with a possibility of doing justice to both. There are many things that might be brought forward on such a border as I have endeavoured to describe, much earlier than is possible where no such position is available. A portion of it may be planted now with Lettuce and Endive, for use in early spring after the frame crops are done; the remainder should be thrown up in a rough condition, for the present. I will, however, return to this subject again as the season advances. Make a last sowing of *Cornflowers* in boxes under glass; sow a pinch of *Veitch's Autumn Giant*, with the other kinds, for coming in in July and August. Where green Mint, Tarragon, Balm, &c., are in demand all through the winter, a few roots of each may be taken up now and potted and pushed on in heat when necessary. Whenever frost is expected some light material, such as "frigidome," or netting, should be at hand to cast over full grown Lettuces to preserve them. A very thin covering will keep off a good deal of frost in autumn, before the earth has parted with its heat.—E. HOBAY.

Curious Artificial Colouring of Flowers.—The "Journal of the French Central Society of Horticulture" has some curious observations on the artificial colouring of natural flowers. Flowers naturally of a violet colour when exposed to the fumes of a cigar assume a green tint, all the more decided in proportion to their original brightness. This is well exemplified in the case of the violet *Thlaspi* or *Iberis umbellata*, and of the *Julienne*, or *Hesperis matronalis*. The alteration in colour is due to the ammonia of the Tobacco. Starting from this point the Italian professor, L. Gabba, has made a series of experiments in order to determine the effect of ammonia on the colours of various plants. Pouring a little ammonia into a plate, and placing a funnel over it, the Professor inserts the flower in the tube of the latter. In this way blue, violet, and purple flowers become of a fine green colour; deep carmine-coloured flowers, such as *Pinks*, become black; white blossoms yellow, and so on; but the most curious effects are produced on parti-coloured flowers, such as red and white when the former colour is changed to green and the latter becomes yellow. Another remarkable example was that of the *Fuchsias* with white and red flowers, which became yellow, blue, and green. When the colours have been thus changed, if the blossom be dipped in pure water it will retain the artificial colour for several hours, and will afterwards return gradually to its natural tint. Another curious observation of Professor Gabba is that *Asters*, which are naturally without scent, acquire an aromatic odour under the influence of ammonia. The same flowers of a violet colour become red when sprinkled with water containing nitric acid; and if enclosed in a wooden box and exposed to the action of hydrochloric acid gas, will in six hours become of a fine crimine colour, which they will preserve if first dried in a dark place and kept dry and in the shade.

Wet Boots.—What an amount of discomfort wet boots entail, and how well we all recall the painful efforts we have now and then made to draw on a pair of hard-baked ones which were put by the fire over-night to dry. Once on, they are a sort of modern stocks, destructive of all comfort, and entirely demoralising to the temper. The following plan will do away with this discomfort:—When the boots are taken off, fill them quite full with dry Oats. This grain has a great fondness for damp, and will rapidly absorb the least vestige of it from the wet leather. As it takes up the moisture it swells and fills the boot with a tightly fitting last, keeping its form good, and drying the leather without hardening it. In the morning, shake out the Oats and hang them in a bag near the fire to dry, ready for the next wet night, draw on the boots and go happily about the day's work.

ON TEACHING BOTANY TO THE YOUNG.

By F. E. KITCHENER, F.L.S.

Is botany, or is it not, a valuable scientific subject for younger boys? In 1867 the report of the sub-committee of the British Association on Scientific Education in Schools, selected botany, together with experimental physics and experimental chemistry, as the three subjects with foremost claims. Mr. Wilson's essay, in "Essays on a Liberal Education," endorsed this opinion, and, by the vivid picture there drawn of possible botanical teaching, contributed to make the world of teachers and of parents expect more out of botany than perhaps experience has shown can be got out of it. A reaction on the subject seems to have set in. Nothing, however, is more unfair than to credit a subject with more than it really deserves, and then to let it suffer from incipient reaction, because it does not fulfil the general expectation. It is worth while, therefore, to see exactly what training botany can fairly profess to give, and to enquire also how far it may fail to do so from not being taught in the proper way. To prevent misapprehension, it will be well to define the pupils to whom the subject is supposed to be taught. I am assuming a class of boys, of from ten to fifteen years of age. In these boys, we may assume the powers of writing and spelling to be, in many cases, feebly developed; but, on the other hand, no one will deny to them quickness of eye, and a natural itching to use their fingers and their knives. Such boys are well suited to take in a subject, which, without requiring any mathematical knowledge, like elementary physics, or any long chain of reasoning like geology, asks at first only for careful observation, comparison, and memory. But again, is our object in these classes to make them botanical collectors, or educated men? If the two objects clash, undoubtedly the latter is the main object; and here at once is a danger—the teacher is probably himself a botanist and in his enthusiasm to make proselytes of the one or two kindred spirits in his class, he may be led to adapt his teaching to the few, and neglect the general culture of the many. In this paper, then, we need not consider the few born naturalists: they will easily be led on by walks and talks till they become botanists for life in heart and soul; but we consider the ordinary boy who will not give you any time out of school that he can help, and whose educational food must be put under his nose, or else he will never see it, much less swallow it. What then are the advantages of botany as it can be taught in classes to such boys as I have described? The main advantage, of course, is that it exercises the powers of observation and comparison. A Dandelion is to a boy a familiar object, but when he has noted all the points that he may be led to observe in its root, stem, leaves, and marvellous head of blossoms, he has learnt that it may be worth while to look more closely at the things around him; in any case, whether he may think it worth while to use it or not, he certainly has improved his power of doing so if he chooses. Even a stupid boy cannot have failed to learn to observe, for he has had to pull his flower to pieces, his own flower and with his own fingers. A clever boy, in the course of dissecting three or four flowers, has learnt a good deal more: he has not only himself observed his own facts, but he has been led to sort them into groups, in fact, to colligate them, and is being unconsciously led up to making the right inductions from them; then the colligated bundles of facts having been stored up, the teacher strikes the match of induction and all the facts blaze into new light: more often the cleverer boys want no match, and the only difficulty is to prevent the fire bursting out before the rest of the class are ready. This exercise in observation and colligation alone seems to be enough to make botany a subject; but the exercise is spoilt if the books put into the boys' hands do all the colligations beforehand. An ordinary botanical text-book handed out to a boy, is like giving him at once a translation for his Greek play, or a key to his arithmetic. He there finds all the botanical facts neatly tied up into bundles, each labelled with its own sesquipedalian epithet. He is not asked, for instance, to examine plants and see what variation is found in Nature with regard to the cohesion of stamens, but is told stamens are either syngenesious or monadelphous. This fault it is for the teacher to remedy—let him from his previous knowledge of the distinctions to be brought out, choose a succession of plants for examination in such a way as to bring successively each of the chief variations under his boys' notice, and then, when they have mentally begun to colligate their facts under heads, *a*, *b*, and *c*, let him supply the terms (or better, their English equivalents), and thus crystallise the knowledge which has been till now in solution. A second great point in favour of botany over other subjects is that whatever advantage may be expected from it can be got at once—no introduction is necessary. The first lesson in botany may be one of the most fruitful, and even as an educational exercise half a dozen lessons may make quite an appreciable difference in a boy's habits of mind. The great drawback to getting the full advantage is the present terminology: what with the difficulties of learning and spelling, the major portion of the time is not given to observation at all, and whereas the

boys would of their own common sense have supplied epithets of their own, and rapidly caught up English names of things, they are weeks picking up the few terms necessary for filling up one of Henslow's schedules. A favourite objection to botany is that it is a complex science of chemistry, physiology, and other subjects presupposing some knowledge. True: but the part of botany which young boys should be taught need not presuppose any special knowledge. In an elementary course of botany, it is doubtless unwise to separate structure from physiology and classification, and it is quite true that boys of the age I am speaking of will be unable to take in the chemistry and physics which underlie the one, or the logical excellence which underlies the other. But while it is difficult to teach young boys how different animals digest, it is easy to show them how they get at their food; and so it is easy to show boys what are the requisites in a plant to secure its obtaining light, heat, and food; and the fertilisation of its seeds and then to show the existence of structure to meet these ends. So again, without taking up classification as a whole, the really natural groups of what we charitably call the natural classification cannot fail to strike the boys themselves, and the teacher, following the order of the growth of classification in the world's history, should at once give a name to the class, and so fix it in the minds of his boys. I should not advise, therefore, that the teacher should attempt to cover all the ground: let him confine himself to what he can teach thoroughly, and that because the boys can take it in thoroughly. Later on in their school life, those who are really taking up the biological side of science, and who have presumably been weeded out by natural selection, may be brought through a second course of botany. They will then know enough of chemistry and physics to fully appreciate the laws of growth, and will value such a text-book as Hensley or Asa Gray, where they can lay their hand on whatever they want in its right place. The difficulty which besets teachers in all subjects, is the pressure put on them by examining bodies to cram and not to educate. This pressure is felt very strongly in botany; if a schoolmaster makes his course of botany really an education to his boys, he yet may leave them unfit to pass an examination in the dry bones of botany, which too often fill up the whole of an examination paper. Examining bodies, even those examining boys under sixteen, seem rather to enforce that the boys should have flitted over many plants and dabbled in many names, than that they should have ever made one single plant their own, by getting up all they can about it. But a good teacher may comfort himself in this; a pupil who has been taught to describe a few plants well, can always describe a new plant at sight, and the practical portion of the paper, the least attempted and worst answered according to my experience as a local examiner, will always bring the well taught boys to the surface. Let us end with a few maxims which will guard against ineffective teaching. 1. No plants should be discussed without, as far as possible, every boy having his own specimen for dissection.—2. No observation should be recorded till every boy in the class has seen it with his own eye.—3. To ensure (2), the classes must be small, or else the lazy boys will evade the teacher, and take their observations second-hand. Much, however, may be done by an assistant-teacher assisting the lecturer by passing from pupil to pupil directing them in dissection.—4. Terms should never be supplied till the things themselves to be named are familiar, and then the English equivalents should be preferred. In fact, such terminology should be chosen as will be picked up at once by the boys.—5. The flowers chosen for examination should be chosen with a purpose, and the ideas of the boys should not be confused, or their memories overlaid, with too many flowers at once: choose your typical forms and keep impressing them on the memories of your boys, till they can schedule a plant of a typical family from memory without mistake.—6. With care and good teaching there is then much to be made of botanical teaching; but whatever is taught must be taught thoroughly. The early part must be known well; it is almost as fatal to neglect the first lessons of botany as it is not to know the earlier propositions of Euclid.—*Journal of Education.*

Wet Coal.—People who prefer wetting the winter's store of coal to the dust on putting it into their cellars do not, we believe, generally know that they are laying up for themselves a store of sore throats and other evils consequent on the practice. But so it is said to be. Even the fire-damp which escapes from coal mines arises from the slow decomposition of coal at temperatures a little above that of the atmosphere, but under augmented pressure. By wetting a mass of freshly broken coal and putting it into a warm cellar, the mass is heated to such a degree that carburetted and sulphuretted hydrogen are given off for long periods of time, and pervade the whole house. The liability of wet coal to mischievous results under such circumstances may be appreciated from the fact that there

are several instances on record of the spontaneous combustion of wet coal when stowed in the bunkers or holds of vessels. And from this cause, doubtless, many missing coal vessels have perished.—*London Medical Record*.

Acres of our London Parks.—Hyde Park contains 380 acres; Kensington Gardens, 290; St. James's and the Green Parks together, 151; Regent's Park, 103; Victoria Park (before the late small addition), 280; Battersea Park, 230; Greenwich Park, 171; Crystal Palace (as originally laid out 100 acres, but reduced to) 168; Alexandra Park (as at first laid out 500 acres, now reduced to) 192; Clapham Common, 190; Wandsworth, 302; Wimbledon, 628; Barnes, 120; Epping Forest, 510; Kennington Common, 15; and Camberwell, 55 acres.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL SOCIETY.

OCTOBER 7TH.

THE exhibition of Fungi held by the Royal Horticultural Society at South Kensington, is generally one of the best supported meetings, if we except those held in the midst of the London season, and although on this occasion one or two of the principal exhibitors of former years were unable to be present, the distinctive character of the meeting was well maintained. Only two exhibitors, Mr. English, of Epping, and Mr. Austin, of Reading, competed for the prizes offered by the society for edible and poisonous Fungi, yet the collections of each were exceptionally good, both containing many new and rare species. Not the least interesting part of the exhibition was the beautiful water-coloured drawings of English and Alpine Fungi, made by Mrs. Chapman, 36, Lancaster Gate. These were specially alluded to by the Rev. M. J. Berkeley in his usual annual lecture on mycology, and greatly admired by the visitors present.

Orchids.—Messrs. Veitch & Sons staged a beautiful group of new and rare Orchids, amongst which were nearly a dozen hybrid varieties of garden origin (see THE GARDEN, Vol. IV., p. 179). Amongst these we noted splendid plant of *Cypripedium Sedenii* (eleven spikes); two fine plants of *Cattleya exoniensis*, the colouring being especially rich, and the petals most delicately frilled along their margins. *Cypripedium Harrisianum* is one of the finest of all Lady's-slippers, and a fresh healthy plant of this variety bore three fine flowers. *Cattleya Fausta*, one of the best of Mr. Seden's acquisitions, was staged in fine condition, and deservedly obtained a first-class certificate; and a noble plant of *Cattleya Domini* bore five or six fine spikes of its soft rosy flowers. *Cattleya Devonensis* and *C. hybrida picta* were also staged in good condition. A fine mass of *Calanthe Veitchii* in flower deserves especial notice on account of its flowering so early; and this suggests how much may be done by a little judicious treatment in the way of forcing, and retarding the flowering season of Orchids, and thus ensuring a longer season of bloom. *Cypripedium Dominicanum*, *C. Ashburtonei*, and a new seedling unnamed, were also shown. The last-named is a cross between *C. Fairrieanum* and *C. insignis*, and its appearance goes a long way towards proving *C. argus* to be a natural hybrid, as we had supposed. A fine mass of *Dendrobium McCarthii*, bearing sixteen flowers, was much admired; while *Vanda cernua*, *Odontoglossum grande*, *O. Roezlii*, *Oncidium bifidum majus*, *Galeandra minor*, *Peristeria elata*, and *Cattleya superba* made up a very important part of the exhibition. Mr. W. Maule, of Bristol, showed a group of ant. Orchids, including *Saccobolium Dayanum*, the curious *Sarcanthus paniculatus*, *Cypripedium caudatum*, *C. Fairrieanum*, *Aerides suavisimum*, and others. A fine plant of *Odontoglossum (crispum) Alexandrae* came from Mr. Toll, of Manchester, with a branched spike fully 1 foot in length, and bearing thirty-three flowers.

Fruit.—The most noticeable specimens of fruit exhibited were three splendid Pines from the Royal Gardens, Frogmore. These consisted of a fine pair of smooth-leaved Cayennes, weighing together 19½ lbs., and a Charlotte Rothschild, weighing 8 lbs. 13 ozs. The system of culture pursued is to plant the suckers out on beds composed of Oak leaves, and where it can be adopted the plan has much to recommend it. Mr. W. Paul staged a large cluster of his new white Grape, Waltham Cross, in excellent condition, the flavour being all that could be desired. This fine late Grape well deserves a place in every Vinery. The same exhibitor also showed a fine cluster of a new white Grape named Winter Muscadine. Mr. Harrison Weir sent a seedling black Grape grown in an ordinary ground Vinery, and named The Artist. The appearance of the Grape is good, and the flavour excellent, but the committee thought it ought to be shown again. Mr. E. Bennett, gardener to the Marquis of Salisbury, at Hatfield, sent three scarlet-fleshed Melons of good flavour. Two fine dishes of Pears named *Beurré Superfin*, and *Beurré des Charnaises* came from the Society's garden, Chiswick, together with some large Gourds. Mr. J. Lewis, gardener to W. T. Price, Esq., Tibberton Court, Gloucester, sent three dishes of Apples for naming. These fruits were fine and appeared to be Catshead, Emperor Alexander, and Blenheim Orange. A dish of large Salway Peaches, rather past their best, came from Mr. B. Blythe, of Woodhampton. Mr. Peter Grievé, of Colford, sent a new seedling Black Grape, with large oblong berries, and a new seedling Pear, named Lucy Grievé, the latter being scarcely ripe enough for judging. Rev. G. Kemp sent a fine Pear, named Pitmaston Duchess d'Angoulême, which, however, was scarcely ripe. A fine dish of Quinces came from Mr. J. Baker,

Shirley Road, Southampton. Mr. W. Maule, of Bristol, brought specimens of his new *Pyrus (Cydonia) Maulei*, which is said to be a highly ornamental flowering shrub, as well as a useful fruit for preserving. Mr. Woodbridge, of Syon House, sent cut sprays of a pretty Hop-leaved Vine, and Mr. Marchant brought branches of *Laurus nobilis*, abundantly furnished with berries.

Miscellaneous.—Messrs. James Veitch & Sons exhibited a very effective stand of the weird-looking Japanese *Chrysanthemums*, the flowers of which are far more ornamental, from an artistic point of view, than those of the common kinds. They are well deserving of culture, as they furnish an agreeable variety. Amongst those exhibited, Elaine is a fine flower of silvery-whiteness; James Salter is a good rosy-lilac; Bismarck, a yellowish-brown; and Blanch of Castile is a fine full flower, the long florets having a peculiarly graceful frill-like appearance. Messrs. E. G. Henderson & Son showed a good collection of Pompon or Bouquet Dahlias in excellent condition, the colours being both bright and distinct, while the flowers are very useful for furnishing either stands or vases during the late autumn months. Several bushy plants of *Pyraantha (Crataegus) japonica*, exhibited by the same firm, were much admired, being densely laden with bright scarlet berries, which looked all the more effective among foliage of a deep and pleasing green tint; it does not appear to be sufficiently well-known that this highly ornamental shrub luxuriates in town gardens, and that its vivid fruit forms a charming contrast to the foliage of the common Ivy, or other evergreens with which it is easy to associate it in many different ways. In the Chelsea Botanic Garden we recently saw a beautiful effect produced by this plant in the manner here indicated. Grafted plants, grown in the bush-like form above alluded to, also make useful decorative plants for citadel halls, corridors, or conservatories during the winter months, especially as they are easily grown on for this purpose in the open border, and can be taken up carefully and potted after the berries are coloured. Mr. W. Paul, of Waltham Cross, sent six stands of cut Roses in excellent condition for the season; indeed Mr. Paul generally manages to wrath the year with Roses quite irrespective of the seasons, and surely no flower is more welcome. Mr. J. C. Crasell, Fairy Croft Nursery, Saffron Walden, showed two or three excellent stands of French and African Marigolds, blooms of the latter being nearly five inches across, and very double. Mr. Marchant, gardener to General Hankey, Sandgate, brought some cut branches of the feathery *Tamarisk (Tamarix plumosus)*. Mr. R. Porter, gardener to Mrs. Benham, Syon Lodge, Isleworth, sent some cut spikes of good seedling Pentstemon and nearly a dozen varieties of *Tropeolums*, some being very rich in colour. A plant of *Rhododendron aureolum* of dwarf bushy habit, with yellow-margined leaves, came from Messrs. E. Jackson & Sons, of Woking.

First-class Certificates were awarded to the following interesting novelties:—

Knapbodia (Tritoma) McDouani (Green).—A dwarf and beautiful addition to a well-known genus of hardy and half-hardy garden plants. It may be described as a miniature *T. Uvaria*, but little over a foot in height.

Vitis heterophylla, var. *lunifolia* (Woodbridge).—This is a beautiful variety of a well-known Japanese Vine, which well deserves general culture for the sake of its fruit-bearing sprays, which are very ornamental, the berries being the size of large Peas, and of a pale blue colour.

Begonia Royalty (Clambers).—This is a dwarf compact seedling, belonging to the now popular tuberous-rooted section of the genus. The leaves are of good substance, and of a rich velvety green colour, the flowers being nearly inches across, of a rosy-scarlet colour, and very freely produced.

Cattleya Fausta (Veitch).—A beautiful addition to the genus, figured and described at p. 135, Vol. IV. It well deserves general culture, as it is a well-tried novelty, and apparently very free both in growth and flower.

Bahia, Sarah McMullen (Rawlings).—A fine well-formed flower, of a bright lilac-purple colour, likely to become popular as a show variety.

PERSONAL.

MR. MARNOCK is engaged in forming a public park at Sheffield, and in remodelling one at Birmingham.—Mr. Meston is to form the new garden on the Thames Embankment, west of Hungerford Bridge. The frequency with which new public gardens have been formed of late years is a good sign.—Mr. John Gibson, jun., is in charge of Hyde Park, Kensington Gardens, and the parks under the same management, during his father's much-regretted indisposition.—Our able correspondent, Mr. R. Gilbert, who has been for some time superintendent of the fruit and forcing gardens to the Marquis of Exeter, at Barchley, is now superintendent of all the gardens there.—Mr. James Drewett, after twenty-four years' service, retires from the management of the Denbies, Dorking. His foreman, Mr. James Beesley, has been appointed his successor.—Mr. James, twenty-six years gardener to the Earl of Dartmouth, at Patshull, retires.—The terrific explosion, which alarmed all London on last Friday morning, took place very near the house of Mr. Edwards, the superintendent of the Regent's Park. He and his family had a narrow escape from death. The house was almost destroyed, yet happily Mr. Edwards received no further injury than some severe cuts and bruises, and it is understood that the other members of the family escaped with nothing worse than a fright.—Mr. Barbidge is engaged on a work on the Daffodils, in which all the species will be represented by coloured plates.—The successor to Mr. Smith as gardener to the Earl of Gainsborough, Exton Park, is Mr. Athorne, who has for some years filled the post of foreman at Arundel Castle.—Mr. Triman, of the British Museum, and Professor Bentley, of King's College, are preparing for the press an illustrated work on medical botany. A work of this kind, from such accomplished and painstaking authors, is looked forward to with much interest.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

A NEW METHOD OF ARRANGING PLANTS.

By JAMES M'NAB, Royal Botanic Gardens, Edinburgh.

PARTI-COLOURED flowers and plants have long been favourites with horticulturists, but a method of cultivating certain Ericaceæ and other plants, by mixing in a growing state the individual specimens of different varieties of the same species, so as to resemble living bouquets, is in some cases more pleasing than more usual arrangements, and is a style that might be more generally practised, not only for effect, but for the purpose of economising space. In villa gardens, which are generally limited for accommodation, this mixed system has often, from necessity, to be resorted to, so any hints tending to further this end may possibly prove useful. One plan of proceeding is the planting together of different coloured varieties of certain Ericaceous plants, so as to form one specimen. A very pleasing appearance is produced by mingling the flower-spikes of the white and red varieties of the *Erica cinerea*, and also the white with the other varieties of *E. cinerea*, which are now very numerous, and which all flower about the same time. The white and pink varieties of *Erica Tetralix* blend well together, also the *Erica Mackayana* and *E. Watsonii*, mixed with the white *E. Tetralix* are very effective. The white and red *Erica vagans* is suitable for the same purpose, as well as the *Calluna vulgaris*, particularly the varieties, *Calluna vulgaris* Alportii, a beautiful red-coloured one, and the *Calluna vulgaris* Hammondii, a pure white sort, being kinds which flower at the same period, as well as numerous others of the same class. With plants flowering at different times, space may be saved, and the same tuft, although composed of two or three varieties, can be made interesting at different periods, depending, of course, on the number of varieties employed. The purple and white varieties of the *Daboecia polifolia*, when mixed, produce an effective plant. The *Daboecia polifolia* versicolor, a variety recently introduced, has the two colours white and purple on the same branch, and even some of its individual flowers are often seen variegated. This beautiful and useful variety is a striking natural example of this bouquet style of cultivation. To carry out the system of mingling colours so as to produce the best effect, the plants ought to be put together in the rooted cutting condition (as recommended in THE GARDEN for December, 1872, and again for August 15, 1874), and worked on as one plant; the branches and roots are thus allowed to get more naturally and freely through each other; all must grow on as one plant, and all must be annually clipped over. When layered plants are put together for this purpose, the twigs do not properly intermix, and the plants, when in flower, are apt to show the two varieties distinct, although in juxtaposition. Such blended colours are very effective in rock-gardens, besides being highly pleasing for clumps, or general border cultivation. In all cases the varieties employed must be exactly of the same height and of the same habit of growth; if otherwise, the harmonious effect will be lost. The mixing of colours to economise space is also very suitable for certain Chrysanthemums, such as the early dwarfs, when grown in pots, of which numerous varieties are now to be had in cultivation; and also with the later-flowering sorts, provided always they are naturally of the same height when in bloom. Cinerarias are very telling subjects when so treated; two or three varieties planted in the same pot, and worked on as one plant, are certainly very pleasing to the eye. In regard to the last-mentioned plant, this system has long been practised in the well managed garden at Inglis Green, Slateford, near Edinburgh, and is now adopted in many gardens, taking care, of course, that the heights of each variety employed should entirely correspond, so as to bring the corymb of mixed-coloured flowers exactly on the same level. The same system holds good with the Chinese Primrose, and many other florists' flowers now cultivated in villa gardens can be treated in the

same way with beneficial results. Local horticultural societies would do well to encourage this system of gardening, as many amateur cultivators with limited plant accommodation can thus grow a much larger number of varieties in a given space than they otherwise could do. Those who have seen Cinerarias treated in this way will, I am sure, agree with me as to the pleasing effect produced by this mixed system of cultivation.

MORNING OPENING OF KEW GARDENS.

EVERY now and then, for some years past, an agitation has sprung up for the earlier opening of Kew Gardens to the public; and we see from the newspapers that the periodical ebullition has lately taken place, and possibly is still going on. Under present arrangements the gardens are opened at one o'clock, and the reform wanted is, that in future the hour of opening should be nine or ten. At first sight the demand seems reasonable. Of two things there can be no doubt, viz., that it would be very pleasant to get in earlier, and that it is a very disagreeable alternative, either (if we know the hour of opening) to have to give up a visit to Kew because the hour is too late to suit us; or (if we do not know it), to arrive at eleven or twelve, and find that the gardens will not be open until one. Although the hour of opening ought to be known by this time all over the kingdom, still new people are always growing up who have not yet learned it, and old people forget what they have learned, and we believe that no day (suited to a visit to Kew) passes without several persons arriving before the hour of opening, and having either to wait or go away—a mishap which one feels the more that there is nothing at hand to assist in whiling away the time (unless, indeed, we have a fancy for tombstones, when we may make a short pilgrimage to the spot where Gainsborough lies in Kew Churchyard). Of course, we all know that there must be some strong reason for such an unusual, and what is apparently such an illiberal and incongruous a rule. It is unusual, for we believe it is the only institution of the kind where this late hour of opening is adopted, unless it be in some small country towns, where the curator of the museum attends gratuitously, and naturally limits his hours of attendance to suit his own convenience. It is unnatural, because in museums within walls it matters little at what hour you go, but in a botanic garden, and especially in such a one as Kew, where science is combined with the beauties of the country and the charms of Sylvan scenery, the morning and forenoon are the hours when these are seen to best advantage, and it is apparently illiberal, because it inconveniences large bodies of the people, and restricts and curtails their enjoyments; and, lastly, it is in the highest degree incongruous, because, in other respects, liberality to the public has been more attended to at Kew than in any similar establishment. It is the only one in this country that is open on Sunday, and in no one is the care for the instruction and enjoyment of the public more conspicuous. The kind of objections to an earlier opening will readily suggest themselves to the reader. It is obvious that there is a great difference between a museum and a botanic garden. The work of the museum is done in the laboratories; there the birds are stuffed and the snakes put into spirits, and the specimens are only displayed after they are completed. In a botanic garden the preparation has to be done in the same place in which the subjects are exhibited. The growing (analogous to the stuffing) is always going on; both bird and plant have to be kept clean, but after the one is on its perch it rests there, whereas, it is not so with the plant, it has to be watered and re-potted, and attended to in various ways. In a word, the laboratory of a botanic garden is mixed up and combined with the show rooms themselves. It is pretty plain that if the working operations of the zoologist had to be conducted in his show rooms there must be some interval set apart during which the public could not be admitted, and much more stringently than in the botanic garden, inasmuch as the work is more delicate and the space more confined; as soon as the public is admitted the zoologist would have to give up work; not so with the cultivator. There is space for him to do much of his work and for the public to look on too. It has been found possible to do so at the Jardin des Plantes and in the Botanic Gardens at Edinburgh and elsewhere. True, nowhere else have

the directors to deal with such vast numbers of visitors as at Kew, but that is a special difficulty, and special contrivances might be adopted to meet it. The great difficulty is the houses. It is clear that the public cannot be admitted to them while the necessary work in them is in progress; and, as they must be all open to the gardeners who are passing to and fro from one to another, it is also clear that one that is in full operation cannot be kept shut to the public, while another not so much occupied might be opened. All must be treated alike, and as large a staff of police watchers would be required for partial opening as entire opening. The expense of police is very great at Kew; we have heard the cost of complying with the petition for early opening estimated at between £3,000 and £4,000, but that was on the footing of a double staff, and on the assumption that as complete a staff should be supplied for the early hours as for those after one o'clock. But it rather appears to us that this is unnecessary. We think that some middle course might be hit upon. At present one portion of the garden is railed off, inside of which no smoking is allowed, but outside of it a cigar is permitted. Within this charmed circle are all the houses, except the new temperate house. Might it not be possible to open the outer part of the garden at ten o'clock, or even earlier, and keep the inner ring closed until one as at present. This would leave only the temperate house out of bounds, and as it is all in one block and under one roof, it might be closed and work go on inside. We believe that opening to this extent would satisfy everyone. For the man of science there is ample employment for the whole morning in running over the out-door collection in the outer part of the garden, and for the general public there is also sufficient occupation. The attitude taken by Dr. Hooker in regard to this question, has been worthy of all commendation. Were the concession granted, it would, undoubtedly, render the fulfilment of his duties much more difficult and laborious, but no opposition to it proceeds from him. How could any? It is merely an extension of the liberal policy indicated by his father, and followed out by himself. So far as the officers of Kew are concerned, it is a mere question of expense, and in that category we venture to think that the increased trouble to the officials ought to be considered. If the necessary means be given them, they can carry the alteration into effect. But as it does resolve itself into a question of means, it would be well for the petitioners to qualify and modify their application so as to reduce the cost of complying with it to moderate dimensions, and we think we have shown how this can be done.

THE NARCISSUS AS A BORDER FLOWER.

ONE of your correspondents recently alluded to *Narcissus poeticus*, the common Pheasant's-eye Daffodil of gardens, as being well worth general culture, an opinion which I can readily endorse. It is one of the most beautiful and fragrant of all hardy flowers, and poets and painters alike have done it honour for ages past. It should find a place in every shrubby border; or, grown in masses, it forms a beautiful object on the lawn, or such portions of it as are not mown until the autumn. It does not, however, appear to be generally known that bulbs of this species force well if they are taken up late in the year, and potted in any light rich soil. Another remarkable fact is, that these bulbs flower better the second year they are forced than the first, so that they should not be thrown away after the first year's crop of flowers is obtained, as is generally the case with bulbs that are forced. Early flowers thus obtained are valuable, as in beauty and fragrance they hold their own with the choicest of all cut flowers. The sort generally used for forcing is *N. tazetta*, a very variable plant, native of the south of Europe, some of the most beautiful and distinct varieties being found on the borders of the Mediterranean. This is the plant so largely imported and sold by our nurserymen about this season of the year, under such names as *Staten General*, *Grand Primo*, *Soleil d'Or*, and *Paper White*. The colour of the flowers varies from pure translucent white to rich golden-yellow, while the corona or cup of some forms is of a rich orange tint, bordering on vermilion. This plant, although generally forced in pots, flowers well in glasses of water, like the *Hyacinth*, while it does well planted out on a warm, moist, sheltered border, and so treated flowers later than the forced plants, so that a succession of flowers may by this latter plan be obtained. A striking peculiarity of this and all the other species of *Narcissus* is, that their flowers last fresh a long time in water. I have had cut spikes in a vase of water for a fortnight, or even longer, and the latest

flowers were then quite fresh. It was formerly the custom of some of the florists near London to grow beds of this plant (*N. tazetta*) out-of-doors for the sake of their flowers in spring, and the flower-spikes were cut from the plants as soon as the first buds had attained their full size. When so gathered, they bear packing better than when the flowers are fully open, and the blooms never fail to open out in succession when placed in water, and flower as well as if left on the plants, and even better, as the flowers suffer from the winds and rains of the spring months. Those who force these beautiful plants should retain the bulbs, and plant them out in a warm border after flowering, as, when so treated, they will in most cases flower well in after years. *N. pseudo-Narcissus*, the common yellow Daffodil, is supposed to be a native of this country, and with its many varieties (both double and single) is well worth border cultivation. It is capable of producing fine effects when planted in masses, a fact noted by several of our poets, from Herrick to Wordsworth, and all lovers of hardy flowers should not fail to read the celebrated ode to Daffodils of the last-named author, which is one of the most interesting and suggestive rural poems in the English language. *N. biflorus* is another reputed native, generally bearing two white flowers on a scape among its wax-like glaucous foliage. It is nearly related to *N. poeticus*, but is readily distinguished by the absence of the purple or crimson ring round the margin of the cup. *N. gracilis*, and its beautiful variety, *N. gracilis tenuior*, also resemble the last in the shape of the flower, and in having a saucer-shaped cup; but the colour is a clear yellow, and the leaves, instead of being glaucous and flat, are semi-cylindrical, and of a vivid shining green colour, nearly like those of the *Jonquil* section. *N. incomparabilis* is a stately species, well worth a place, its flowers varying from deep yellow with an orange-margined cup, to pure white with a lemon cup. The flowers are solitary, on stout scapes, 16 to 18 inches high, the flowers being about 3 inches in diameter. There are two or three very distinct and beautiful double-flowered varieties of this plant, the flowers of which are very showy, and these should find a place in every herbaceous border. One of these has white segments, partly encompassed in a glowing orange neteary or cup, and is the *Double Orange Phoenix* of old florists and gardeners. A yellow form, with a deep orange cup, is the *Sulphur Phoenix*; and there is another still paler form than either, very beautiful, although now seldom seen in cultivation. The flowers of these are nearly as double as the *Rose*, and so heavy that they require some support to prevent them bending to the earth. A white-flowered kind, somewhat similar to the last, has nodding white flowers, with a cylindrical cup; this is *N. poeciliformis* or *N. montanus* of gardens, and is interesting to botanists and amateurs on account of its flowers being rarely perfect, having often only three or four segments instead of six; and the drooping character of the flower is very distinct from any other species, and serves to distinguish it from the last-named plant. The gem of the whole genus is *N. triandrus*, a pale sulphur-yellow-flowered plant with from two to five flowers on a scape, and deep green rush-like leaves. This has recently been re-introduced to cultivation, and is one of the prettiest in the whole group. The segments of the perianth are reflexed so as to give the flower the appearance of a yellow *Cyclamen* or *Dodecatheon* rather than a Daffodil. The flowers of this species are very delicate in structure, yet it has proved to be one of the hardiest, and withstands sun and rain better than most of the others. *N. Jonquilla*, the common *Jonquil*, is well known as a border plant, its bright yellow flowers being borne in clusters on slender scapes among a tuft of deep glossy green rush-like leaves. It forces well, and its fragrant flowers are always welcome for the flower vase in early spring. Nearly related to this plant, but with larger flowers, is *N. odorus*, or *Campanelle*, a showy plant largely grown in some old market gardens for the sake of its deep golden sweet-scented flowers. Like the last-named species, it is often met with in the double state; but all its forms are beautiful, and it well deserves more general culture. *N. juncifolius* is a pigmy only an inch or two in height bearing two or three pale yellow flowers on a slender scape. The flowers somewhat resemble those of *N. Jonquilla*, but the cup is very much larger in proportion to the size of the flower. It is not showy, but deserves a corner in every garden where choice hardy bulbs are appreciated. Of all the *Narcissus*, however, there are few better than *N. Bulbocodium*, the *Hooped Petticoat Daffodil* of gardens, which often flowers almost before it frees itself of the surrounding earth, each flower glowing like burnished gold. This does remarkably well in pots for conservatory and greenhouse decoration, and it should be grown in quantity everywhere. Of all hardy flowers, if we except the *Broom*, we know of none of a richer yellow colour than this species. A variety (*N. monophyllus*) with white flowers comes from Algeria, but it does not grow so freely as the yellow-flowered form. All the varieties of this plant are tender, and often perish during cold wet winters unless protected by a mulching of dung or leaves.—*The Gardener*.

BEDDING VIOLAS AND PANSIES.

DURING the past season large numbers of these have been tried at Chiswick, and late in the summer, too late to fairly test the merits of the early-blooming kinds, the floral committee paid the collection a visit, and awarded certificates to the following, viz.:—Tyrian Prince, purple-self Pansy; Imperial Blue Perfection Pansy, blue-lilac; Blue-Bell Viola, bluish-lilac; Lily White Tom Thumb Pansy, pure white; Miss Maidland Pansy, white, with a veined eye; Mulberry Viola, mulberry-purple; The Tory Viola, large purple-blue; Chieftain Viola, lilac-purple; Dickson's Queen Viola, white, dark eye; Dickson's Golden Gem Viola, bright yellow; and Dickson's King Viola, light purple. Among these Golden Gem, is a rich yellow variety that presents considerable improvement on *Viola lutea grandiflora*. Still better, in my opinion, is Royal Sovereign, another of Dickson's varieties, the blooms of which are golden yellow, large-rounded, and produced in abundance. I am surprised that Miss Maidland received a certificate, as it sports badly, many of the flowers coming much splashed with purple, and of the four plants upon which judgment was passed at Chiswick one at least had all the blooms thus discoloured. I can but conclude that the certificate was intended for Delicata, which was growing next to it and which was, at the time of the committee's visit, in beautiful condition. Some varieties that are generally of superior quality were not quite in good condition just then, and of these none have been prettier than Corisande, the flowers of which are pale primrose-yellow. This is an exquisite kind, and gives a hue of colour hardly to be met with in any other bedding plant. Yellow Boy is meritorious as an early flowering variety, and is one which cannot be excelled for spring blooming. Blue Bedder is another very early kind which makes a capital spring bedder. For continuity of bloom, however, none can excel *Viola Blue Bell*, as it flowers at least three months longer than any other blue Viola in cultivation. Among other good kinds sent by Messrs. Dickson, were Queen of Lilacs, the flowers of which are of medium-size, opening pale purple and turning to lilac; Advancer, mauve flaked with blue, free grower; Vanguard, rich purple-crimson; and Alpha, blue with a small blotch, a free grower. From Mr. Cocker, of Dundee, have also come many fine varieties, too late, however, to have their merits fairly tested. Of compact white self Pansies, Mrs. Smith and Mrs. Sutherland are both good; Mrs. Carson has large deep blue flowers; The Member has blooms pale blue in colour, much like those of Blue King; Bon Accord and Keepsake are both of the same type as Mrs. Carson, and strong growers; the Shah was one of the most striking kinds; its flowers are large, round, and of good substance, and of a deep maroon-purple colour; Profusa is a large robust form of *Viola* magnificent.

THE VARIEGATED CORNISH MONEYWORT.

This is one of the most charming novelties we have met with, even in these days of wide-spread taste for hardy variegated plants. The Cornish Moneywort is a modest little plant, long grown in Ferneries, and among Alpine plants, owing to its graceful form and interesting character as a British plant. Nevertheless, not possessing any brilliancy of flower it has never become a very popular plant. Its delicate fresh green, however, and the facility with which it grows in any place where hardy Ferns succeed, should make it more popular. We have seen it thrive vigorously in a London area, the plant falling down and draping the pot with a mantle of charming verdure. In a wild state it creeps about in shady places, the banks of rills, and like positions, along the western coasts of Europe, extending as far north as the southern parts of England and Ireland. It is found also in the Channel Islands. This new variegated form is likely to be much more popular; its leaves are prettily margined with white, and this marking seems, in all cases, regular. Our illustration, however, gives a good idea of the variegation and general character of the

Variegated Cornish Moneywort.

A. D.

plant. It is engraved from a small specimen brought under our notice by Mr. David Syne, manager of the Lawson Seed and Nursery Company, in whose Edinburgh nurseries the stock of this charming novelty is growing. It will, probably, in addition to the purposes for which the green *Sibthorpia* is grown, be found desirable for surfacing pots and baskets in the greenhouse and Fernery, and for concealing pots and other objectionable surfaces; its dense mantle of leaves keeping very close to the surface, and the growth being of such a nature that it will not rob the soil of the nutriment required by other plants.

THE WOOD OF THE DOUGLAS FIR OR OREGON PINE.

THE wood of this Fir is very strong, clean, free from knots, and straight in the grain, whilst the great lengths in which it can be obtained, straight and sound throughout, mark it out as well adapted for purposes in which joints would, in all probability, be a source of weakness, if not of expense, in consequence of the extra labour involved. Take, for example, some timber roofs of over 95 feet span, lately constructed for portions of the new building at Alexandra Park. If the tie-beams had been cut out of Oregon Pine logs, the

central scarfed joint, with its fish-plates of iron and wood, might have been dispensed with; though, no doubt, it would have been necessary to reckon the expense of sawing the stuff down to the required scantlings, since logs of such a length would have run to a correspondingly large sectional area. Logs of Oregon Pine can generally be found floating in the basins of the Surrey and Commercial Timber Docks, but chiefly in what are termed Oregon masts, which are roughly hewn to an octagonal section, so as to allow of their being readily rounded off for masts and spars. It predominates in the forests of the West Cascade region, but not in the arid parts of the East Cascade region. It is plentiful in Washington Territory (United States). The Douglas Fir is also found in some of the Rocky Mountain valleys, on the Blue Mountains of Oregon, and here and there eastward as far as the head waters of the Platte. At present the principal seats of its manufacture for export are the coast of British Columbia, and in Puget Sound (United States). The Douglas Fir does not grow in any quantity north of Millbank Sound, in latitude 52°. The principal existing mills are in the New Westminster district, and probably that neighbourhood will continue to be the chief seat of the export of Douglas Fir. The Nasse-Skena district looks like a good saw-milling country on the map, but the Douglas Fir, as just said, is not found so far north. The

inlets on the mainland, or some of the outlying islands between Millbank Sound and the new Westminster district, probably offer locations for export saw-mills, but it is not known, however, at present, that these places can be found readily. Many of the inlets are almost wall-sided, with short water-courses or torrents emptying into them, the water collected among the surrounding gloomy mountains. The rivers generally which flow into these inlets are not good "logging" rivers. There is, however, a vast extent of water-line between Millbank and new Westminster.

Natural Meteorologists.—It is said that a leech, placed in a bottle of water, remains at the bottom coiled up and motionless, if the weather is fine and the barometric pressure high. If rain may be expected during the day—which corresponds in general to a diminished pressure of the air—the leech rises to the surface of the water, and remains there until fine weather. If wind is approaching the leech darts about with great velocity. If a tempest is to be expected it remains out of the water, and experiences a kind of convulsions and violent agitations. In snow and prolonged rain the leech fixes itself at the orifice of the bottle. In permanent frost it remains at the bottom. On the contrary, a frog descends to the bottom before rain, and arises to announce fine weather.

NOTES OF THE WEEK.

— MR. DAVID THOMSON informs us that Pearson's Golden Queen promises to be a grand late yellow Grape. It is a seedling between Ferdinand de Lesseps and the Black Alicante. The bunch and berry are exactly like those of the Madresfield Court, but in colour bright yellow. The flavour is said to be excellent.

— AMONGST plants now in flower on the rock-work at Kew, may be mentioned the showy tuberous-rooted Begonias, which are blooming freely, while the pretty little *Nertera depressa* is one mass of rich orange-tinted berries, strewn over a carpet of the freshest green. *Crocus longiflorus* is also effective, and late-blooming *Cyclamen* promise soon to be very ornamental.

— THE large Vinery in the Royal Horticultural Society's garden at Chiswick is just now well worth a visit. It is the largest house devoted to Grape-growing in the country, and when the immense crop of handsome fruit, which it annually produces, is ripe, its appearance, especially to any one who sees it for the first time, is very striking.

— HAMBURGH GRAPES, from the original locality for the cultivation of this fruit, are now plentiful in Covent Garden. They come in steamers from Rotterdam, and are of very good quality. The way they are packed deserves notice. They come in circular baskets, without any packing material whatever, a sheet of white paper serving to keep out the dust. The lid of the basket fits firmly down on the Grapes; thus packed, they come much better than many Grapes sent from gardens in the home counties, wrapped in swaddling clothes of various kinds. These usually serve to remove the bloom and lower the market-value of the fruit.

— MR. YATES, of Sale, Cheshire, has sent us some remarkably fine plumes of *Celosia pyramidalis*, the colours of which are golden-yellow, crimson, and purple, of the brightest and most striking description; when well grown, as in the present case, these feathery Cockcombs form valuable decorative plants for the greenhouse or conservatory during the summer and autumn months, and deserve more general cultivation than they receive. Mr. Frisby, the gardener at Blankney Hall, Mr. Henry Chaplin's seat, in Lincolnshire, grows these admirably, so large, indeed, that his plants are in habit and grace more like good specimens of *Humea elegans*, than what we are accustomed to see as *Celosias*.

— WE have received, through Messrs. Veitch, some well-grown pitchers of different kinds of *Nepenthes*, grown by Mr. David Thomson, of Drumlanrig, among which, two splendid ones of *N. distillatoria* each held fully a pint of water, while others of *N. rubra*, *N. Hookeri*, *N. Rafflesiana*, and *N. ampullacea* were also fine examples of their respective kinds. A leaf of *Rafflesiana* (not including the leaf-stalk nor any appendage) measured 19 inches in length, and 11 inches in breadth, and the pitchers of *distillatoria* were produced, we understand, 22 feet from the pot in which the plant grew, and which was a 13-inch one.

— FROM a paper on "Some Indigenous Tuscan Remedies," read by Mr. H. Groves before the Pharmaceutical Conference, it would seem that plants furnish much of the medicinal products in use in that country. Many of the plants enumerated are well known as medicinal plants in other parts of Europe. The *Chamomile* (*Matricaria chamomilla*), for instance, is said to be found in the cupboard of every housewife, being used as a calming antispasmodic, and also applied hot externally for relieving pain. A custom very prevalent in Tuscany seems to be the administration of herb-juice in spring, which is prepared daily by many herbalists, and is also ordered by medical men. *Nasturtium officinale*, known as "Cressone," is used in conjunction with *Cochlearia officinalis* in the composition of herb-juice. This latter plant, though indigenous, is also cultivated to some extent. The flowers of the Wallflower (*Cheiranthus Cheiri*), under the name of Yellow Violets, are boiled in olive oil and used for emmata.

— ON Wednesday the Right Hon. the Lord Mayor, Sir Andrew Lusk, M.P., and the Lady Mayoress entertained the Master, Wardens, and Court of Assistants of the Fruiterers' Company, in accordance with an ancient custom, at dinner at the Mansion House. The dinner was served in the Egyptian Hall, and was principally given to the Fruiterers' Company in commemoration of the settlement long ago of an old grievance between them and the Corporation, arising out of the Lord Mayor for the time being from year to year in ancient times claiming a metage on fruit brought into the City market. This impost became so irksome to the traders that at length it was commuted into a voluntary offering by them to the Chief Magistrate annually of a choice selection of fruits of the season, he in turn inviting them to dinner at the Mansion House. We are not aware that the Fruiterers' Company ever do anything for fruit-growing, or fruit-growers, or even take the trouble to allude to either of these. We presume they have, in the course of time, become possessed of

much property, some of which is devoted to dinners costing £200 or £300 or so for themselves and their friends. However, this ignoble way is, after all, only what is followed by similar bodies.

— THE Royal Imperial Horticultural Society of Vienna has initiated a movement for the erection of a memorial in honour of the renowned horticulturist Siebold, in his native town of Würzburg.

— MESSRS. VEITCH have issued a coloured illustration representing their new Tea Rose, Duchess of Edinburgh, which is a good representation of this fine and distinct Rose.

— THE stately white flowered Feverfew (*Pyrethrum uliginosum*) is now finely in flower both at Chiswick and elsewhere. It forms, where well-established, a dense bush 4 or 5 feet high, and well deserves a place in the most select collection of herbaceous plants.

— A SEVENTH edition of "The London Catalogue of British Plants" has just been issued by Mr. Robert Hardwicke. This, the seventh edition, is made to correspond with the "English Botany" of Dr. J. T. Boswell-Syme.

— AN important sale of hardy plants is to take place at the Sunningdale Nursery, on the 19th inst., and, that in addition to many thousands of shrubs and other stock, various trees specially prepared and selected for avenues will be sold in large quantities.

— THE true Jalap plant (*Exogonium Purga*) is now blooming freely on a south wall at Kew, where its rich purple salver-shaped flowers have a beautiful appearance. Independent of what other properties it may possess it is well worth attention as a tender or half-hardy climber. Jalap has been in the European *Materia Medica* for the last two-and-a-half centuries, but, until comparatively recently, the plant that yielded it was unknown.

— JUST now, when most bedding plants are on the wane, or are already unsightly, it may be useful to direct attention to some splendid beds of Pansy Blue Bell, which are now in bloom at Chiswick. This variety is dwarf in habit, and forms a dense mass of rich purplish-blue, and, when combined with Golden Pyrethrum, some very striking autumnal effects might be produced. As a late bloomer this Pansy is one of the best we have yet seen.

— WE have received from Mr. Yates, of Sale, Cheshire, well-grown specimens of the Comte de Lamy Pear, a kind distributed by the Royal Horticultural Society many years ago; and an excellent Pear, although not so extensively grown as it ought to be. It is a medium-sized, roundish-obovate shaped kind, white when sent and richly flavoured. Mr. Yates has grown it for market purposes, in the form of standards, for years, and finds it excellent in his district.

— HERBACEOUS ASTERS, or Michaelmas Daisies, as they are popularly called, are just now amongst the most effective of all late autumn-blooming plants. Of these, there are collections at Chiswick and at Kew, both of which are well worth inspection by all interested in hardy border plants. One of the best is Chapman's Michaelmas Daisy (*Aster Chapmani*), now flowering in the herbaceous ground at Kew. It is a tall kind, bearing pale bluish flowers, and is well fitted, either for the backs of borders or for naturalisation.

— IN our report of the Royal Horticultural Society's meeting, which took place the other day at South Kensington, we inadvertently omitted to mention Carter's Green Gage Tomato, a new kind, which, on account of its singularly delicious flavour and distinct character, was awarded a first-class certificate. Since then we have received from Messrs. Carter specimens of this Tomato, which certainly possesses a peculiar and very agreeable flavour. In colour it is pale yellow, smooth, round, and about the size of a large Orleans Plum. To us it seems good enough to use as a dessert fruit.

— PLEIONE WALLICHII is just now blooming freely in the Orchid-house at Kew. The bulbs are grown in small pots, and these are judiciously suspended level with the eye, so as to be readily seen by the visitor. This is an example worthy of imitation in gardens both public and private. *Cattleya Pinellii* and *C. (Laelia) Perrinii* are also in flower, together with many other small flowered, but singular, species of botanical interest, including the curious green-flowered *Epidendrum diffusum*, and *Polystachia grandiflora*, bearing a large inverted flower at the base of the thick leathery leaf.

— A SAGACIOUS correspondent of the *Builder*, writing on the proposal to improve Trafalgar Square, remarks:—"There being some prospect of a change in the stony aspect of the most central of London squares, I venture to protest against the proposal of planting shrubs round the Nelson column. This would hide its proportions, and is every way objectionable. If the lions require some protection from rough usage, a moat filled with water would be more suitable, and might be supplied from the waste of the fountains." A moat would be a nice addition indeed to the attractions of Trafalgar Square in the nineteenth century. A good many clever persons are supposed to suffer from being born before their time, but this one we should not place among them. All interested in gardens, public or private, have much reason to exclaim, "Save us from the kind intentions of architects and builders!"

THE INDOOR GARDEN.

BEST GLOXINIAS.

THE following varieties have been in cultivation during the past two years, and have proved to be both useful and attractive:—Duchess of Athole, white and porcelain-blue; Mrs. Downie, white and crimson; The Shah, rosy-crimson, throat deep crimson; A. H. Bridges, cream throat, the month and lobes soft purple; Rev. H. H. Dombrain, crimson-lake, white throat; and Violet Marquise, rich violet with white throat, are all fine drooping varieties. Of the erect-flowering kinds the following can be very highly recommended:—Grand Monarch, dark rich purple, margined with white; Brilliant, dazzling scarlet, edged with carmine; Emperor of Brazil, deep violet and white; Purple Prince, white and deep violet; Sidonie, white, stiped with lavender; and Thomas Lobbs, dark violet-blue, with pale blue margins to the lobes. The foregoing would make a select and extra fine collection both for exhibition and decorative purposes. Supposing a cultivator has a select number of fine varieties, and it is his desire to propagate any of them, the best plan is to attempt it by means of the leaves. If the leaves be taken from the plant at any season of the year, cutting them away with a piece of the stem adhering, inserted singly in small pots in some light sandy soil, and placed in a brisk bottom-heat, they will soon root and make rapid growth. Now, the Gloxinia has been so much improved upon, and seeds so freely, that a pinch of seed will be certain to furnish some very fine varieties; and there is the additional pleasure of watching for new beauties to unfold themselves. The seed of the Gloxinia is as easily raised as that of the Chinese Primula. If a pinch of seed be sown in March in a pan of fine soil, and covered with a sheet of glass or a bell-glass, and placed in a Cucumber-house or a propagating-pit, it soon germinates. As soon as the plants are large enough to handle, they should be pricked out into shallow boxes in a fine soil consisting of peat, silver sand, and thoroughly-decayed leaf mould, and grown on in a brisk bottom-heat. In June the plants will be fit to put into 48-sized pots, in which they will flower during August, September, and October. A packet of seed saved from a good strain will produce flowers both of the drooping and erect-flowering varieties. The best time to propagate from leaves is in the spring, as good flowering plants are thus obtained for the summer which follows. The Gloxinia is impatient of water at all times, although it luxuriates in a humid atmosphere. If too much is given at the roots, the plants soon decay; therefore, it should be administered always with caution, and never till they are dry. Syringing overhead, though recommended by some growers, should be withheld while the plants are in flower; only let there be a humid atmosphere. This is essential to the well-being of the plants; in a dry atmosphere the leaves are apt to become infested with red spider, and get a very sickly appearance. A soil composed of fibrous peat, leaf mould, well-decomposed sheep manure, with a very liberal addition of silver sand, is that best suited for Gloxinias. They should not be potted into large pots unless the plants are very strong; 48 and 32 pots will be found quite large enough for general purposes. When the plants die down at the end of the summer, after flowering, they may be stored away in a dry place under the stage of a stove, or on a dry shelf, till they are wanted for re-potting. If a succession of bloom is required, some of the tuberous roots should be potted in January, and successional batches in February and March; these will yield a good supply of beautiful flowers throughout the summer, and, while they last, will be always gay and effective.

R. D.

PHILODENDRON SELLOWIANUM.

THIS, though an extremely effective plant, is rarely seen in sub-tropical collections in this country; it is, however, frequently met with in Continental gardens, both as an open air decorative plant during summer, and as one for the ornamentation of conservatories and apartments during winter. It grows quickly in a moderately warm temperature, throwing up dense green leathery foliage on all sides, and forming a very symmetrical plant, such as that shown in the accompanying illustration. Like its congeners, it luxuriates in a rich warm soil; and, while growing, requires plentiful supplies of moisture at the root during hot weather. Unfortunately, it is rather difficult to propagate, a circumstance which may in some measure account for its scarcity; still offsets are occasionally produced by well-established plants, and, if liberally treated, these grow rapidly and soon form well furnished specimens, while plants of this Philodendron used for sub-tropical gardening in summer, are effective for conservatory decoration in winter, their deep green singular looking foliage having a pleasing appearance intermixed with that of other plants.

B.

DRAINAGE AND WATERING OF POT PLANTS.

WE are so accustomed to the practice of growing plants in pots, that many people, I dare say, have come to regard the flower-pot as almost essential to the culture and well-being of hot-house plants—to think, in fact, that a plant in a pot is more favourably circumstanced than it could be in any other way. This, however, is a mistake. The flower-pot is certainly indispensable in some cases, but, after all, it is but an imperfect contrivance, and it will, perhaps, surprise some to be told that a plant could scarcely be placed under conditions more inimical to its welfare than when it is growing with its roots in a flower-pot. Its existence, under such circumstances, is altogether a question of unremitting attention and skill, and not unfrequently these are unequal to the task of maintaining robust health, which might be secured without difficulty if the pot were discarded and the plant placed under natural conditions. I might instance such plants as the Camellia, the Orange, or the Luculia, all of which attain a degree of vigour and luxuriance, when planted out, unknown to specimens grown in pots. Some would, perhaps, ascribe the difference to freedom of root-action in the former case, and restriction in the latter; but this is not the whole explanation of the matter, for a plant makes most roots in a pot, and it can be fed liberally with liquid manure and other stimulants. Besides, that restricted root action has little influence either one way or the other is proved by the fact that when the pots are plunged in some medium, such as earth or ashes, the plants grow nearly as vigorously as when planted out altogether. It is the extremes of temperature and the irregular condition of the soil as regards moisture, to which the roots are subjected in a pot, that operates injuriously upon the plants. The common earthenware pot absorbs much of the water that is supplied to the roots, and, being an active conductor, evaporation is continually going on from its outer surface, robbing the roots packed against the inside of both heat and moisture to an extent just in proportion to the position the pot occupies. In a conservatory, for instance, where the ventilation is abundant, this cooling and, under some circumstances, almost freezing process is constantly in operation, and is only counteracted by unremitting attention to shading and watering. The direct evils arising from this unavoidable state of things are the attacks of insects—aphis, red spider, and thrips—mildew in some subjects, and

Philodendron Sellowianum.

in plants such as Heaths, Cinerarias, and Calceolarias very often death. Indeed, all, or nearly all, the evils to which pot-grown plants are subject are traceable to the pot system, or to the practices it entails, among which drainage and frequent watering must be reckoned the most important. Let us consider the drainage question first.

The greater proportion of plants, whether grown for fruit or flowers, which are cultivated in pots require liberal supplies of water in order to keep them in health, and the only object of draining the pots with crocks, cinders, or other materials in the usual way is to carry off surplus water and prevent it stagnating about the roots. But some carry this system of drainage to an extravagant length. Whether the pots are great or small, they insist upon filling them a quarter or one-third full of crocks, as if there were a possibility of water stagnating in any but a compost of the most tenacious description, and forgetting entirely that the evaporation from the sides of the pot is almost sufficient in itself to prevent even a large ball of soil from ever becoming unduly saturated, except through careless watering. No pot requires more drainage than is just needful to allow the surplus water that is given in watering to run off readily; and a very few crocks will permit this if they are clean. Great pains are not unfrequently taken in draining pots for Pines, pot Vines, and such like, resulting in nothing that I ever could see but waste of time. All that is necessary in pots of the largest size is to put a good piece of crock over the hole in the bottom, concave side downwards, and on the top of this, half-an-inch, 1 inch, or 2 inches—according to the size of the pot—of crocks that have been put through a half-inch sieve and cleaned. This is all that is required, and the operation can be performed in about one-fifth of the time usually taken to build the superstructure of pieces, great and small, that many consider essential. I drain everything in this way from the tub, downwards, and for the most select subjects, and never knew the drainage to get choked in a single instance. As for small pots up to 4½ inches, I rarely use more than one crock, and for the thousands of bedding plants we get up every year no crocks are used at all. Why should we crock a 1-inch pot with a hole in the bottom of it, and which does not contain more than a handful of soil, and presents nearly a superficial foot of evaporating surface all round? The difficulty I find is to keep such plants moist enough before bedding time; yet I know that in places where bedding stock is raised by thousands, every pot is crocked in the most patient manner, and when the plants are turned into the beds the crocks in each have to be again carefully removed—all of which is lost labour and nothing more. And now as to watering. If we want a lesson, we cannot do better than take notice under what conditions as to moisture plants thrive best out of doors. In a healthy soil, unless it is just after heavy rains, we never find the soil so saturated as to feel cloggy in the hand, as the soil about pot-plants often is through over watering, causing the surface of the ball and sides of the pot to become green and soured—a state of things in which no plant, not being a marsh plant, can long exist in a healthy state. To ensure watering being efficiently done at all times, no pot should be filled up to within less than half-an-inch or two inches of the rims, according to the size of the pot. This point is often overlooked by operators who do not take time to think of the after inconveniences which result from such neglect. When great numbers of pot Strawberries, pot Vines, and such like come to be watered frequently during the growing and fruiting periods, the evils of over-potting become apparent, and to save labour with the watering pot, saucers beneath the pots become a necessity; whereas, if sufficient space had been left for watering, they would not have been required, for saucers are an evil, owing to the danger of water standing about the roots.

I force many hundreds of Strawberry plants every year, but by careful potting, and by arranging the plants on the shelves so that they may have as much shade as possible, I never require to use a single saucer to hold water. The best time to water plants is early in the morning, before the drought and heat of the day are felt, or late in the afternoon, when ventilators are closed and evaporation is reduced to a minimum. The water should always be, as nearly as possible, of the same temperature as the air of the house in which the plants grow; and this may always be ensured conveniently by having a tank in the house big enough to hold sufficient water for at least twenty-four hours supply, so that it can be filled once in that time, and the water left to get warm before it is used. It will be found highly advantageous to the plants upon shelves and airy stages to arrange them so that the foliage of one specimen will shade the pot of another. It is the sun and air playing upon the roots of plants so situated which does the mischief; hence the practice of plunging the pots wherever practicable, but which cannot always be done; and shading is the next best plan. The great advantage of shading the pots, when plants are growing, I have signally proved over and over again, in the case of Strawberries especially. Instead of placing

them widely apart in rows after potting, I set them closely together in broad squares, and in this way they shade each other effectually, and the sides of the pots are always cool and moist; they do not need to be so often watered, and the plants grow vigorously, the outside plants invariably being the weakest and most stunted, and requiring to be watered nearly twice as often as those inside the square. In September, in order to harden the roots and ripen the crowns, I thin the plants out a little, say from 6 to 8 inches apart, always retaining the "square" arrangement till they are housed in October. By this treatment I get Black Prince Strawberry plants with leaves like Keen's Seedling, and crowns as long and as thick as my thumb, with a potful of healthy roots. This treatment, which suits the pot Strawberry so well, would be found equally beneficial with all pot plants. Watering regularly and abundantly should be the rule; but no plant should be watered till it is needful, while at the same time watering must never be delayed till the soil becomes parched, and the extremes from heat to cold and from draught to saturation will be avoided.—*Field*.

WINTER CULTURE OF MIGNONETTE.

Few flowers are more esteemed for bonquets in winter and early spring than Mignonette; it is also very useful for the decoration of the drawing-room and conservatory at those seasons of the year. Although Mignonette is not a delicate plant, yet it is not generally seen in the perfection to which it might be brought by good culture. To flower at or soon after Christmas the seed should be sown earlier than this, say about the beginning of August, in pots of any convenient size. The soil should be good loam, moderately enriched with rotten dung, and kept open by a pretty liberal intermixture with old mortar or lime rubbish. It is essential that the pots be thoroughly drained, and upon the drainage a handful (more or less, according to the size of the pots) of one-year-old pigeon's dung should be placed. After sowing the seed, set the pots where they will not require frequent waterings, too much moisture being extremely injurious to Mignonette; for this reason, therefore, it will be safer to place the pots in a frame or pit, where they may be covered by the lights in rainy weather. As the plants increase in size they should be gradually thinned, ultimately leaving three or five in each pot. The principal point to be attended to now is judicious watering; by this I mean giving water only when the plants really require water, and then in sufficient quantity to moisten the whole of the soil—not dribbling a few drops over the plants to-day to prevent them from being dry to-morrow—a practice too much followed with plants in pots. Pinch off any premature flowers that may appear, keep the pots free from weeds, and far enough asunder to prevent the plants from being crowded, and when they are removed to winter quarters, set them near the glass in an airy situation. A few of the plants might be placed in an intermediate house, or other situation rather warmer than a greenhouse, to come into bloom a little earlier than the rest. I have recommended the seeds to be sown in the pots, which is the method I prefer; but, if more convenient, a sufficient number of self-sown plants might be taken up and potted, only a few extras should be put in to allow for casualties, as Mignonette transplants badly. The best Mignonette I ever saw was treated in this way; but as it is not every one who can procure pigeon's dung, I may add, that guano will be found an excellent substitute. This must, however, be applied in a liquid state, and not before the pots have become well filled with roots, when a small quantity of guano, given at intervals of a week or so, will increase the vigour of the plants in an extraordinary degree. A second crop might be sown in the beginning of September, and managed in the same manner. Single plants will attain a large size in 32 or 24-sized pots, if the main branches are pegged down as they grow and the flowers are kept pinched off for a time. The beginning of January is early enough to make the first sowing for a spring supply. The pots for this sowing should be from 4 to 6 inches wide, and should be filled with soil to within half an inch of the rim, then press it evenly and firmly, and on this sow the seed regularly; and, if its quality can be depended on, eighteen seeds will be enough for each pot—they will come up with more strength than if sown thicker. Sift a little soil over them and give a gentle pressure with the hand, leaving the surface smooth and even; then water with tepid water, which will warm the soil and assist germination; plunge the pots in a frame with a gentle bottom-heat, and give but little air until they begin to appear: afterwards give ventilation more freely, avoiding at all times the admission of cold air in great currents, as Mignonette suffers very much from rash exposure in that way. When the plants become a little hardened take off the lights every fine day from eleven to one o'clock, which will prevent them from being drawn, and better enable them to support themselves. As soon as the seed-leaves are fully developed, thin out the

plants, leaving at this time twelve or thirteen in each pot. This number should be kept for a while, as they are liable to damp off, if the weather should happen to be wet and dull. When they have made four or five leaves, thin them out to seven plants, which will be quite sufficient. At the same time, stir the surface of the soil, which generally becomes hard by continual watering, and thereby prevents the access of air to the roots. When the sun begins to act powerfully upon them, a thin shading for two or three hours during the heat of the day will be of service. When they have attained the height of 3 or 4 inches, they should be tied up, to prevent them from falling over the sides of the pot; in doing this, put six small stakes, at equal distances, close by the edge of the pot; then pass a strip of matting with a turn round each of the stakes, and fasten it; the stakes should be left 3 inches at least higher than the plants, as they will require a second tie. If the roots have now found their way through the bottom of the pot, they must be broken off, or the plants will receive a great check when finally removed. In replanting, give them sufficient room to prevent their being drawn; they will require great attention till the beginning of May, when they will, if properly managed, be in good condition for removing to the greenhouse. The next sowing should be made in the latter end of March. Successional sowings may be made about the latter end of May.

W.

SIPHOCAMPYLUS BETULÆFOLIUS.

This is a well-known South American plant, specifically distinguished by its Birch-like leaves. It forms a dense-branched shrub, which, under good management, is covered, from early spring till late in

Siphocampylus betulæfolius.

autumn, with bright scarlet-tinted yellow-lipped blossoms. Our illustration represents the end of a branch furnished with flowers, which, springing from the axils of the leaves, contrast very strikingly with the foliage. Young plants of it obtained now will make good sized specimens next year. During winter they should occupy a situation somewhat near the glass, in a house where the temperature may range from 45° to 55°. Care must be taken not to overwater the soil at this season; but an occasional sprinkle with the syringe on the mornings of bright days will be beneficial, especially if the plants exhibit any signs of the approach of their enemy, the spider. As early in spring as is convenient place them in a moist growing temperature of from 60° to 75°. Examine the state of the roots and shift into the flowering-pots, if the balls are full of active healthy fibres; but if otherwise, repair the drainage, clearing away any unkind soil, and defer shifting until space is wanted for the roots. After shifting, the plants should be neatly staked, keeping the branches rather thin, and any over gross shoot should have its point pinched off, with a view to equalise the growth, and secure well-formed compact specimens, which this will tend to effect. The spring treatment may be moist and warm, if growth is desired, but if the object is to have the plants

in full flower early in the season, they should be placed where they will receive all the light which can be afforded them, with a free circulation of air on every favourable occasion, and a rather dry warm temperature may be maintained, but in this case it will be necessary to use the syringe freely, for if spider obtain a footing at this season it will be a lasting pest, and also disfigure the handsome foliage. During the summer months flowering specimens may occupy a situation in the warm end of the greenhouse, or elsewhere, where they can be screened from the mid-day sun, and where they will not be exposed to drying currents of air. If it is wished that the plants should continue producing flowers during the autumn, they must be removed to a situation where the night temperature may range as high as 50°; and, if this is maintained, they will flower throughout the autumn and winter. But if not wanted for autumn blooming, they should be removed to a situation where the temperature may range about 45° at night, and they should not be over-watered. With a small shift annually, they will last several seasons; and if they appear bare and unsightly, they may be cut back, and after they start into growth the balls may be greatly reduced, which will render them as good as young plants. Firm pieces of the young wood planted in sandy peaty soil, covered with a bell-glass, and plunged in a gentle bottom heat, root freely; or strong plants are speedily obtained by layering a shoot on the surface of the pot. Good turfy peat and loam in about equal proportions, with a liberal admixture of sharp silver sand and lumpy bits of charcoal or potsherds, will form a suitable compost for the growth of this plant. Another species of this genus, *S. penduliflorus*, has very long climbing branches, and pendent panicles of carmine-red flowers. J. S.

Solanum lycioides.—What is this? I have a good collection of *Solanums*, and one bearing this name. Can you furnish any account of it?—DOWNE. [It was found by Hartweg, in the valley of San Antonio, in Peru, and flowered at Chiswick some years ago. It has a neat habit; the leaves are lanceolate; the flowers are of the richest sapphire purple, enlivened by a bright yellow eye, and, in the wild state, appear in clusters so numerous as to load the little spiny branches. The name is a happy one, for in its natural state it is very much like a dwarf *Lycium barbarum*. In cultivation, however, it loses some of its stiff spiny habit. It is by no means new to Europe, for it was represented in Jacquin's "Figures of Rare Plants" more than sixty years ago, but it has disappeared from most of our gardens. It is a greenhouse plant, which appears to succeed in almost any kind of soil, but to prefer sandy loam mixed with a little rough peat. To flower it well, it seems necessary to place it out-of-doors during summer, in some exposed situation, where it can remain till the end of September. By that time the flower-buds will be formed, and they expand in a short time after the plant is taken indoors.]

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Fuchsia procumbens.—Of this new Fuchsia we have recently seen a nice stock in Mr. Kinghorn's Nursery at Richmond. It is a gracefully drooping species well worth culture, even if none of its little yellow, purple-tipped, blue-anthered flowers were produced. It is readily propagated, and as a basket plant deserves a place in every greenhouse. It has been exhibited at South Kensington, and was much admired.

Wintering Caladiums.—I should be obliged if you would tell me the proper way of treating *Caladiums* at this time of year. I have never yet succeeded in preserving the tubers.—GREAT MALVERN. [After the plants have died down naturally, lay the pots containing them on their sides on a shelf or under a stage, in an intermediate house, but not near hot-water pipes, which would dry them too much. Laying the pots sideways keeps the root from suffering from drip. Thus treated, we have never known them to fail. Some growers, however, turn them out of the pots in which they have been growing and store them in a box of sand.]

Stove Plants for Winter Blooming. E. S. The best are *Euphorbia jacquiniiflora*, *Eucharis amazonica*, *Gesneria exoniensis*, *Gardenia florida*, *C. citrodora*, *Lucuba gratissima*, *Poinsettia pulcherrima*, *Plumbago rosea*, *Eranthemum pulchellum*, various *Epphyllums*, *Ureolina aurea*, *Franciscia confertiflora* and *calycina*, *Stephanotis floribunda*, *Aphelandra cristata*, *Imantophyllum miniatum*, *Clerodendron Balfourianum*, *Impatiens Jerdoniae*, different kinds of *Amaryllis*, *Centradenias*, *Centropogon lucayanum*, *Conoclinium lanthum* and *atrorubens*, *Ixora amabilis*, *aurantiaca*, and *javanica*; various *Rogerias*, *Rondeletia speciosa major*, *Scutellaria Mociniana* and some others, *Sericographis Ghiesbreghtiana*, *Siphocampylus nitidus*, *Thyracanthus rutifolius*, and two or three sorts of *Toxicophleba*.—J. BEXTER, Pine-Apple Place.

Lobelia Lady Macdonald.—This new *Lobelia* at present occupies a conspicuous position in Messrs. Downie, Laird, & Laing's winter garden, in Edinburgh. Its flowers somewhat resemble those of *L. Paxtonii*, but individually they are much larger than those of that variety; the three lower petals of each bloom measured collectively about an inch across. It is, however, if anything, lighter in colour than *Paxtonii*, and is delicately suffused with blue. It is an abundant bloomer, and, as a *Lobelia* for pot-culture, surpasses anything in that way I have seen. Apart from the usefulness of *Lobelias* in the flower garden, they make, as is well-known, valuable vase-plants, and they are equally useful for intermixing with foliage and flowering plants in front rows on the shelves of greenhouses and conservatories; for such purposes *Lady Macdonald* will be found invaluable. It obtained a first-class certificate at the Royal Caledonian Horticultural Society's show on the 9th of September, and its merits do full credit to the award.—J. MEIN, Clovenfords.

THE FRUIT GARDEN.

VINES IN GREENHOUSES.

THE Vine has been more or less successfully cultivated in Pine-stoves, but its culture in the greenhouse has not been attended with equal success. This may proceed from various causes, such as the condition of the Vine-border, improper temperature and aëration. If the border be imperfectly drained, or the soil exhausted, the first thing to do is to remove the earth of the border to the depth of 3 feet, if on a sloping surface, but if flat 2 feet will be quite sufficient. It should not be less than 15 feet wide. It is impossible to lay down an invariable rule as to the depth of soil which ought to be removed in every case, but I wish it to be distinctly understood that it is not necessary to dig a deep pit, as some do, for the purpose of filling it up with a mass of materials through which the sun's heat will never penetrate; for, although such a border may be made of the best composition, it cannot be called a good border. When the old soil is cleaned out, a good drain should be made along the front of the border. In forming a new border, the bottom part should have a good slope, and should be covered about 10 inches deep with rough stones. Over the stones place a covering of Furze, with the bushy side uppermost and the woody part under. A row of turf should be placed upon the Furze, with the grassy side downward. This will form an effectual and a permanent drainage to every part of the border. The new border should be composed of fibrous turf, leaf soil, and horsedung, which should be filled in to the depth of 4 feet, as it will finally subside to about 3 feet. It is unnecessary to prescribe the proportions to be used of the above ingredients, as that must depend on circumstances. Leaf soil is generally a scarce substance; and, therefore, should the loam be of a strong quality, it should be mixed with light soil, as much of a vegetable nature as possible, keeping in view the principle that the composition should be sufficiently porous. If the old Vines have been growing in a wet soil, or a great portion of their roots decayed or rotten, I would recommend in planting them to lay a portion of the stem across the border and peg it down with strong pegs about 6 inches deep. As to what length ought to be laid down in this manner that will depend on the state of the old Vine. The lower part of neglected Vines is generally bare of young wood, perhaps half-way up the main stem. Some of the spurs beyond that may even be exhausted. I would therefore plant so as to have a good fresh shoot at the entrance of the Vine into the house, or, at least, at the foot of the rafter. This shoot should be cut down to two or three eyes, and, if all go on well, it will grow from 20 to 30 feet the first season. If young Vines are required (and, upon the whole, they are best, if the old ones are not in good condition), good strong ones should be procured from a respectable nursery and planted in spring. The roots should be well spread out, and 3 feet of the stem should be laid down horizontally 6 inches deep in the ground. The sorts most suitable for a greenhouse are—Black Hamburgh, Black Prince (Hamburgh), and White Sweetwater. I would advise that the border should be covered with a light covering of dry leaves, or leaves and dung, about this time of year, and a covering of water-proof canvas or wooden shutters should also be applied to carry off heavy rains. The covering should be removed about the middle of May, when the border should be forked over, and it should be frequently stirred during summer, but especially after heavy rains.

J. H.

A Large Peach Orchard.—Mr. Shellcross, who resides near Middletown, Delaware, owns one of the largest Peach orchards in the world. Last year he shipped to New York 125,000 baskets of fruit, and it is estimated that he lost, by being unable to procure labour to pick, about 25,000 baskets more. On several days he loaded from his orchard ten railway waggon loads. Mr. Shellcross's orchard reaches along the public road for more than 8 miles—generally on either side—and covers an extent of upwards of 1,000 acres, on which is growing more than 100,000 trees.

Victoria Nectarine.—This Nectarine is one of the best varieties in cultivation. It is a strong grower, an extraordinary bearer, and the fruit is large and of first-rate flavour. I am not acquainted with any other variety that stands heavy cropping year after year like it, and, at the same time, swells its fruit so well. We have one small tree here that was planted in 1866—a young plant, and which has borne every year since—generally a fine crop for the size of the tree. This season it had above twelve dozen fruit upon it, all large, and made a strong growth at the same time. I should mention that the fruit never acquires its full colour and flavour while on the tree. The shady side is always green when the fruit is fit to gather, but it gets well flavoured and a high colour after it has lain in the fruit room a few days. The Victoria is a second early kind, and should be

leisurely ripened, with plenty of air, and the fruit should be well exposed to the sun, when it acquires a deep red colour on the sunny side. I have kept the fruit a fortnight or more after gathering in the fruit-room, and six weeks in a box in the ice-house.—J. S. W.

Thinning Fruit Blossoms.—Some of the older writers on fruit culture suggested that in the case of fruit trees that did not set their fruit well, it was of service to thin out the blossoms or to pick off the early petals of the flowers to ensure the remainder setting well. Mr. Du Breuil, has been experimenting in this matter. In 1872 he operated upon twenty espalier Pear trees of the Doyenne d'Hiver Pear, taking out the central blossom from each bunch of flowers on every alternate tree in the row. When the fruit was gathered he found that there was no perceptible difference either in the quantity, the quality, or size of the fruit. In 1873 he repeated the experiment upon twelve trees, operating upon an alternate six. In this case the trees operated upon produced sixty-five fruits, and the six not operated upon produced sixty-eight fruits. He therefore concludes that, whilst the theory appears rational enough, practice does not sanction its correctness; and that the operation has no influence upon the abundance of the product.

Pasturing Cows in Apple Orchards.—In riding through Normandy last autumn—a country filled with orchards—from the Apples of which cider, the universal beverage of the district, is made, the writer saw a great number of cows pasturing on the rich Grass under the trees, and eating the fallen Apples. Every cow was rigged with a sort of rope harness, to the girth of which was attached a short halter that prevented her raising her head to take Apples from the trees. The contrivance was exceedingly simple and cheap, and there is no reason why it might not be adopted by cultivators in this country, who would gladly pasture their orchards except for the damage done to fruit and branches by cows whose heads are free. The halter should be as short as will allow the head to be raised to its natural level; there will then be no danger of its being caught by the foot. This is not only more effective, but much less objectionable than the method sometimes practiced of tying the halter to one of the forelegs. The cow, when harnessed in this manner, walks about, lies down, and rises up, with perfect freedom.—*Agriculturist*.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

What to Grow Under Vines: W. W. H. You cannot get plants to grow well under the shade of Vines. There are plants that at certain seasons require the same treatment. When, however, forcing the Vines, all sorts of flowering plants could be forced too, but as soon as the Vines are in full leaf they should be taken out. In winter, Vineries not having fruit in them can be used as ordinary greenhouses.

Frogmore late Bigarreau Cherry.—This, of which a coloured plate is given in this month's *Flora*, is said to be a very useful late variety, which hangs long on the tree without cracking, a fault belonging to the old Bigarreau. The fruit of this late kind is large, bluntly heart-shaped, with a slight suture. The skin is pale waxy-yellow, covered with bright red on the sunny side; the flesh is tender and juicy, and in every way excellent.

Early Normandy Plum.—A Plum bearing this name has been originated in France. The early season at which it ripens may render it worth cultivating in this country. It is thus described:—Tree, a very vigorous grower, with long branches somewhat divergent. Fruit, as large as that of a Greengage, divided on one side by a very slight suture. Skin, fine, transparent, separating readily from the fruit when ripe, of a clear purple colour on the sunny side, and light flesh-coloured on the shady side; covered with a light bluish bloom. Flesh, fine and melting, of a greenish colour, somewhat firm, filled with a very abundant sugary refreshing juice. It ripens from the middle to the end of July, and this, together with its size, handsome appearance, and good quality, render it valuable. We have no large Plum of the same character which ripens so early.

Pear Culture in Japan.—"Occasionally," says Mr. T. Hogg, who knows Japan well, "as you pass along, you see orchards of trained Pear trees, of the kinds peculiar to the country. The trees are planted, as nearly as I could judge, from 12 to 15 feet apart. After attaining the proper height, the tree is allowed to form branches, and these are trained to rough framework of the same height, perfectly level, and extending over the whole area of the orchard. What object the cultivator has in training them in so careful manner I have not as yet ascertained; but why may it not have its advantages in enabling him to secure his crops in the highest possible condition? Every fruit is thus brought into view, and within reach of the gatherer, who, where trees are left to grow in their natural form, too often runs the risk, in order to secure some tempting prize displaying its beauties on some inaccessible branch, of injuring the tree, or worse, possibly himself.

The Hoolbreuk System of Fruit Culture.—A year or two ago a new system of fruit culture, practised by a peasant on the Danube, was introduced to the public by "*Les Mondes*." The system consists essentially in training the branches of fruit trees, Vines, &c., so as to give them an inclination below the horizontal line, in which case there is, it is said, a great increase in the fertility of the branch. An essential condition of the process consists in having the line of the branch nearly straight, as, if curved, only the buds at the top of the arch are developed, while the rest remain in their original condition. In an instance related by a Mr. Thoreau, he took four Vine plants and trimmed them, so as to have one stem to each, and trained them each a different way—vertically, obliquely upwards, horizontally, and obliquely downwards. He found that from the limb inclined downward more than three times as much fruit was produced as from the others. Doubtless this, or a modification of it, has been often tried with us. It is, perhaps, however, worth a systematic trial.

THE FLOWER GARDEN.

TREE WEIGELAS.

THESE can be made in the following manner:—Strike cuttings of the young wood at the middle or end of summer. They will root very easily in a frame or under a bell-glass on the shady side of a hedge or fence. In the spring, plant them in rich, deep soil, and a warm, sunny situation. Before winter, they will form a vigorous little bush. In the following spring, manure the ground, unless it is extremely rich; and cut down the bush to within an inch of the surface. It will at once begin to throw up a number of strong succulent shoots from the crown of the root. When these are 2 or 3 inches long, slip off the smallest and weakest of them; then choose out the strongest and most upright shoot, and pinch off the tops of all the rest. If they were all removed at once, the supply of leaves would be insufficient to meet the demands of the root, and the vigour of the plant would be diminished; but as the chosen shoot grows, and develops its leaves, the rest should be pinched back, and finally removed entirely, though not all at once. The chosen shoot is now left alone, drawing all the nourishment of the root, and nourishing it in turn by the broad, healthy, deep green leaves with which it is furnished from top to bottom. It will throw out side shoots, but these should be slipped

head from 12 to 18 inches in diameter, which will bloom abundantly in the next summer. Thus you obtain a tree some 4 feet high instead of 6 or 7 feet. A row of such trees planted at intervals along a garden-walk would be a very attractive object, and they would not interfere much with the flowers below. The old *Weigela rosea* is not suited to this use. We have found the best varieties for trees to be *W. grandiflora* and *W. Desboisii*. *W. Isoline* also answers pretty well, though it does not make so straight and clean a stem. Probably the large, strong-growing *W. arborea* would do extremely well; though we cannot answer from experience. All these are robust in growth, with a tendency to form straight upright stems. Other species and varieties, such as *W. multiflora*, *W. hortensis nivea floribunda*, and the variegated-leaved varieties of *W. rosea*, might be grafted on them as stocks.

F. PARKMAN.

AMPELOPSIS TUBEROSA AND NAPIFORMIS.

A. TUBEROSA, though not quite hardy, is a plant well deserving of attention; it has slender branches and smooth, glossy, much divided leaves. Its roots, which are tuberos, are generally united together at the shoulders, into an irregular mass, deep red or brownish in colour; in texture they are cellular, and contain a good deal of

Tubers of *Ampelopsis tuberosa*.Tubers and leaf of *Ampelopsis napiformis*.

off as fast as they appear, as well as all shoots from its base. It will thus grow from the top alone, and, by the end of the season, will form a straight stem 6 feet or more high. This is the trunk of your tree, the top of which is formed during the next season in the following manner:—Rub off all the buds that begin to grow along the stem to within a foot or more of the top. Here many buds will rapidly develop, and push out on all sides into succulent shoots. When these are about 6 inches long, pinch off the tips with the thumb and finger. This will cause them to branch; and the branches, being treated in the same manner will branch again. Thus, before the season is over, you will obtain a compact head round, or of any shape you please to make it; for, by this system of pruning with the finger and thumb, you can completely control the growth. Your tree is now complete, and, the next summer, will astonish you by its mass of bloom. It will continue, however, to develop for several years; being kept in shape by finger-pruning, and all side-shoots from the stem being rubbed off. Such a tree requires three years from the planting of the cutting for its formation; but a smaller tree may be made by the end of the second year. To do this, pinch off the top of the young stem when it is from 3 to 4 feet high and in full growth. This should be about the end of July. It will soon begin to throw out branches at the top, which should be pinched back as before directed. In October it will have formed a

mucilage something like that found in the roots of the Chinese Yam. *A. napiformis* is a hardier plant than *A. tuberosa*, but closely resembles it in appearance, and, like it, is deciduous. Its roots, which are Turnip-shaped, are arranged in clusters, fleshy and brittle, and covered with a wrinkled brownish skin. They are also abundantly stored with mucilage, similar to that of *A. tuberosa*. Both these species of *Ampelopsis*, which are natives of China, may be increased by means of cuttings put in in spring, and struck under a bell-glass. A peaty soil suits them best when young; but when established, they may be planted out-of-doors in summer, when they will succeed in good garden mould. Both kinds possess considerable interest as outdoor climbers in warm situations.—*Revue Horticole*.

Wintering *Salvia patens*.—In reference to your remarks on this subject (see p. 340), I may add that I have wintered this *Salvia* as follows:—After the stems were cut down in October, the plants were lifted and the soil shaken from them. The roots were then planted thickly in a bed of fine soil in a cold house (a cold frame would answer equally well), and, with the exception of a good soaking of water occasionally, just to keep the soil moist, they received no further attention during the winter. Early in March, the young growths began to push through the soil, and by the end of the month hundreds

of strong cuttings may be had if required. Early in May I take the plants carefully from the bed, divide them with a sharp knife, and plant them. Some time ago Mr. Falconer called here, and he then stated that *Salvia patens* was so far hardly in the north of Scotland that the roots were allowed to remain in the ground all winter. Last winter, therefore, I allowed two long rows, each containing about 100 plants of it, to remain where they had been growing all summer. As soon as the stems had been cut off a ridge of earth, about 6 inches in thickness, was thrown up over the roots, and this was allowed to remain until the end of last March; then, on a dry day, the soil was carefully levelled with a fork, and by the end of April young growths had come through the ground in great abundance; and, although we had some severe late frosts, no material injury was sustained. This summer the plants grew robustly and bloomed profusely, suffering less from drought than usual, a circumstance doubtless owing to the fact that they were well established. I am, therefore, of opinion that the roots of *Salvia patens* are quite as hardy as those of the *Dielytra spectabilis*, and that if the crowns be protected with a small heap of ashes, they will not be injured by frost. My plants this season must be lifted as soon as cut down by frost, as the ground they occupy is required for a different purpose. I shall merely, however, transplant them thickly into some light soil under the boughs of an overhanging tree; and, in the event of sharp weather, protect them by means of a little dry litter.—A. DEAN, *Bedfont.*

The New Pelargonium Society.—This deserves the cordial support of all interested in the cultivation of Pelargoniums; for owing to the vast numbers of them that are yearly "let out," purchasers want some trustworthy tribunal on whose decisions they may depend. There is now so little difference between some of the stage varieties and the Zonal class, that the latter name has but little significance. Zonals, indeed, might not inaptly be termed "perpetual flowerers," possessing, as they do, such a floriferous habit. But apart from this, would it not be well to elect the opinions of growers in various districts, as to the varieties of which they most approve as "borders." In this estimate they should take into account habit, brilliancy of colour, continuity of bloom, and profusion of flowers. The exposure to which they have been subjected might be named, and whether grown upon strong or light soil. This would be necessary, as soil, situation, and other local circumstances effect such a change in certain kinds. I believe that such an election, properly carried out, would not only prove highly interesting, but instructive. The electors should be requested to name such a number in each section, as may ultimately be determined upon, as, for instance:—Six Scarlet Zonals, four Golden Tricolors, four Silver Tricolors, two plain Golden-leaved kinds, two Bronze Zonal, two Rose-flowered sorts, and two White. On this proposal, I shall be glad to have the opinion of some of your correspondents.—GEO. WESTLAND, *Witley Court, Stourport, Worcestershire.*

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

New Variegated Snapdragon.—I have sent you leaves and a flower of a variegated *Snapdragon* which came up among a batch of seedlings in a nursery in Shropshire. The bloom is crimson, with yellow mouth, and the leaves have a deep cream-coloured edge, and are sometimes slightly variegated. The habit of the plant is dwarf and the variegation constant; it grows well, and is very hardy. It is eminently adapted for borders in winter, the green in the centre of the leaf contrasting well with the light edge.—H. S. NEWELL, *Bishops Cleeve.*

Goldilocks (*Chrysocoma Linosyris*).—This is just now in perfection on the Orme's Head, Llandudno, North Wales, and I believe Llandudno to be its most northern habitat in our island. Perched high up among the grassy nooks and corners of the carboniferous limestone rocks, its yellow flowers are very beautiful; indeed, I consider it to be one of our most attractive composites, both in its golden blossoms and its deep green flax-like leaves, which are simple, and dotted over with glands both above and below. I have not often seen it wild in this country, but here it flowers and flourishes in the greatest luxuriance. I made its acquaintance on the Orme's Head many years ago, when I first found the rare *Cotoneaster*, growing in the same wild scraggy ground as on the Continent, and *Silene maritima* nodding over the ledges of rock, and attracting such flights of insects in the twilight of a summer's evening. *Rubia and Helianthemum canum*, and *Veronica spicata*, and *Chlora*, and *Hippocrepis*, are all here, and each has often been gathered by me in my summer rambles in Carnarvonshire many years ago.—PETER INCHURCH, *Llandudno.*

The Sea Bindweed (*Convolvulus Soldanella*).—Permit me to say a few words about this pretty native Bindweed, the large pink blossoms of which are a great ornament to our sandy sea-shores in the summer months, putting forth, as they do, rich bright flowers from the barren drifting sand. But I wish now to speak of the economy which this plant displays in autumn, when the bright flowers are over, and the seed-vessels appear. These are, as in the *Cyclamen*, so deflected that the capsule is buried in the sand, and thus the process of expansion and maturing takes place. On the sandhills on Conway Bay, in North Wales, I have recently had abundant opportunity of noticing Nature's process in perfecting the capsules of *C. Soldanella*. Many, indeed, were nearly buried in the sand. Each capsule contains four seeds, which are black when fully ripe. I collected some scores of these seeds. The leaves of this Bindweed are like those of the Alpine *Soldanella*, hence the name.—PETER INCHURCH, *Llandudno.* [It is indeed a charming plant, which, unlike many other Bindweeds, never becomes troublesome as a weed, and it is quite easily grown in any light soil.]

THE HOUSEHOLD.

Preserving Tomatoes.—The following is the method by which the excellent tins of preserved Tomatoes now found so good in winter are prepared. They are first slightly scalded, sufficiently to peel nicely, and when peeled, are thrown into pans in order to let some of the watery part drain off. They are then packed into 2½ pound cans, leaving just room enough for a large spoonful of syrup. This syrup is made by dissolving 2½ pounds of salt, and the same amount of sugar, in one gallon of water. The cans are then sealed and placed on sheet-iron pans, holding thirty-five cans each, and lowered into a vat containing boiling water of sufficient depth to cover them. If a can is not tight, it may be readily discovered by the air which will escape through the hole, causing bubbles to rise to the surface of the water. The leaky can should be immediately taken out and the hole stopped. All kinds of vegetables and fruits put up in cans, should be first tested in this way before they are bathed. When a vat full of Tomatoes has thus been tested and prepared, the pans are lowered into the vat, one top of the other, and the steam let on, allowing the Tomatoes to boil thirty minutes. In case cans larger in diameter are used, longer cooking will be necessary. When the Tomatoes are done, the pans and their contents are hoisted out, and the cans, after they have cooled a little, are vented by opening the prick-hole in the cap with the soldering iron, allowing the steam to escape, and then immediately closing the aperture. When the cans have cooled, if all right, the heads will snap in by a slight pressure, showing that there is a good vacuum.

Origin of the Use of the Tomato.—In August, 1826 or 1827, Andrew Parmentier, who owned the Horticultural Garden at the junction of the Flatbush Road and the Jamaica turnpike, in Brooklyn, asked me to call and see his Tomatoes. The stems were carefully trained on the south side of an embankment of small stones. The first two feet was covered with large, bright, red fruit, which would average, at least, half a pound each. Up to the very stems, for 2 feet or more, they were turning yellow, and green as much farther. They were not smooth, but very much convoluted, and out of shape. Some of the skins were bursting from pressure within, which Mr. Parmentier considered perfection. Mr. Parmentier gave them away very freely among his friends, most of whom liked the attention better than the Tomatoes. Mr. Parmentier was justly very highly esteemed by the horticultural gentlemen in New York, especially by Dr. Howard, Dr. Stephens and his brothers, Hugh Maxwell, Esq., and others. They all tried to eat Tomatoes for Mr. Parmentier's sake, as he was sanguine that it was the vegetable for America, if once accustomed to them. A horticultural dinner was got up expressly to eat these Tomatoes, and the gentlemen and ladies ate them as a compliment to Mr. Parmentier, making as few wry faces as possible. When I next met Mr. Parmentier, he said, with much confidence, that the time would come when Tomatoes would be as common and as cheap as Potatoes, and as universally used. I had previous to this known a species of Tomato, called love Apple, raised as a curiosity, and eaten by some for its supposed medicinal qualities.—MR. SWAIN, in *Cultivator*.

Chestnuts.—This abundant fruit may claim a place, not equal to that of the Haricot certainly, but still an important place, amongst the substitutes for Potatoes. The roasted Chestnut is well known in England, but in France and many other countries it is an important article of consumption. The sale of roasted Chestnuts in Paris is enormous. But the Chestnut, indeed, enters regularly into French cookery; it is used to make stuffing for turkey, and from it is made a *purée*, named after the great Condé, who was a famous *gourmet* as well as a general, which is eaten with many dishes in place of mashed Potatoes, and is much liked by those who relish a certain amount of sweetness in such preparations. Boiled Chestnuts are also eaten largely in some districts, connoisseurs adding a little butter to them when cut open, but utterly repudiating salt with them, in which we think they are decidedly wrong. In Corsica they form a large part of the food of the country, and in the south of France, and in Spain, they are largely consumed. The Chestnut certainly ranks among the most wholesome and nutritious of fruits, and deserves more consideration than it receives in English houses.

To Cook Rice Properly.—The following is the method recommended by the French Academy for cooking Rice during the siege of Paris. Put one cupful of Rice and one-fourth of a cupful of water in a saucepan, cover and place it over a good fire; after an hour the water will be evaporated, and the Rice cooked tender, but dry, and with the grains distinct, not in a paste. Sufficient salt should be added in the first place, and care should be taken not to disturb the Rice while cooking. By adding a little butter, and allowing the Rice to dry a little more over a gentle fire, a more delicate dish is prepared.

THE LIBRARY.

VAN HOUTTE'S FLORE DES SERRES.

THE third quarter of the twentieth volume of this richly-illustrated work has reached us. With the exception that six of the plates in the parts now under notice are again taken up with Pears, which we cannot but consider out of place in this work, and that no fewer than five of the other plates are re-productions of plant portraits which have already appeared in the *Botanical Magazine*, the plates are most of them exceedingly interesting, and, as usual, specially remarkable for the beauty and delicacy of the colouring—points in which this work excels, by a long way, any other with which we are acquainted. Plate 1 faithfully represents perhaps the most showy member of the Silene family, known either as *S. Hookeri* or *S. Bolanderi*, introduced to our gardens by Professor Bolander, who sent seeds of it to Kew, collected by him on the wooded coasts of Plumas, in California. It is believed to be perfectly hardy, and is now, we believe, to be seen in bloom on the rock-work at the Royal Gardens. Plate 2 represents *Pentstemon Palmeri*, a fine addition to our hardy border plants, introduced to this country by means of seed sent from Utah and other parts of North-western America by Mr. Watson. It is a tall, strong-growing species, producing fine thyrses of bloom, of which the throat is creamy-yellow and the inside of the upper lip bright magenta, with a pale rose-coloured under lip. It is a most ornamental species. Plate 3 represents *Cypripedium arietinum*, a small and insignificant variety of Lady's-Slipper, with dull greenish upper petals and a small whitish slipper, faintly streaked with rose-colour. It is indigenous to North America and Canada. Plate 4, represents a charming miniature Irid from the Cape, named *Syringodea pulchella*, with grassy foliage and rosy-purple Crocus-like flowers. Plates 5 and 6, represent *Doryanthes Palmeri*, an exceedingly handsome and showy member of the *Amaryllidaceae* family. It is a native of Australia, and in this country grows well in a temperate house, requiring, however, to be of a considerable age and size before it can produce its splendid spikes of deep blood-red blossoms, with a pure white centre, produced in clusters of two or three blooms on the terminal foot or 18 inches of a stem of from 11 to 12 feet in height. Plate 7, represents a rather pretty member of the *Melastomaceae* family, named *Brachyotum confertum*, and also known under the names of *Chatogastra* and *Rhexia conferta*; it much resembles *Genetyllis talipifera* in the shape of its blossoms, which are purple, with a conspicuous white calyx. Plates 8, 9, 10, 11, 12, and 13, represent Pears in fifteen varieties. Plate 14, represents *Masdevallia Houtteana*, a most curious variety of this interesting family, producing medium-sized white blooms, thickly spotted with bright rose colour, and with three bright rose-coloured tails hanging from each bloom, presenting a most singular and unique appearance. It is said to thrive in a cool greenhouse. Plate 15, is a portrait of a member of the *Liliaceae* family, known under the names of *Cyclobothra lutea*, *C. barbata*, and *Fritillaria barbata*. It is a native of the Mexican prairies, and produces, somewhat freely, pendulous blooms of a deep yellow. Plate 16 is a portrait of *Aquilegia leptoceras chrysanthra*, the beautiful Golden Columbine introduced from New Mexico and the state of Arizona, and we think hardly does justice in clearness and brilliancy of colouring to this fine addition to our hardy garden border plants, which is so free-flowering and so easy of cultivation that it should be found in every well-stocked garden. Plate 17 represents *Seaforthia elegans*, a most beautiful and graceful Palm from Australia, which, from its ornamental foliage, is likely to be useful for room and table decoration, as it thrives in a low temperature. Plate 18 represents *Odontoglossum Rossii majus*, a beautiful Orchid from Mexico, first introduced under the name of *O. Ehrenbergi*, and of easy culture. Plate 19 represents *Aristolochia tricandata*, a most curious species of this extraordinary and generally attractive family, but of somewhat more distinct and conspicuous colouring than is usually found among them, introduced from the forests of Chiapas, in the extreme east of Mexico, by Ghiesbreght, who sent it to M. Verschaffel, of Ghent. It requires the temperature of a stove, as do all this family, with the exception of *A. Sipho*, which is hardy. Plates 20 and 21 represent *Stanhopea Martiana*, a handsome species of this genus of Orchids. Plates 22 and 23 represents a bunch of Grapes and foliage, the berries of which are not remarkable for size, but for having deep-red juice, and whose foliage turns a fine red in autumn. This Grape is also said to make good wine, but is useless as a table fruit. Plate 24 is a portrait of *Calochortus Leichtlini*, a beautiful variety of this lovely family of Californian bulbs, producing large pure white flowers with a clearly marked deep maroon spot at the base of each of its three petals. It is almost hardy, requiring only the protection of a cool greenhouse or cold pit. Plate 25 is a portrait of the beautiful *Erythronium grandiflorum*, producing from eight to ten of its handsome pure white flowers on stems from 18 inches to 2 feet in height; it is a

native of the Rocky Mountains. Plates 26 and 27 represent the handsome Indian Cycad, known as *Cycas circinalis*, said to be the finest of its family, and requiring only the temperature of a temperate house. The natives of the parts where this species is indigenous, make its pith into a kind of sago, and use its leaves for thatching their houses; the down of its foliage they weave into stuffs for garments; with its leaf-ribs they make ropes, and its nuts, when roasted, form one of their favourite foods. W. E. G.

LESSONS TAUGHT BY THE LATE DRY SUMMER.

THROUGHOUT the greater part of the country drought has been severely felt this summer; in some parts it has been disastrous to the farmers, and, coupled with dry and frosty nights, it has had disastrous effects on nursery stock and on gardens generally; wherever trees and shrubs have been recently moved on any extensive scale, even those moved early last autumn with balls, and which looked quite fresh up to the middle of April, though quite taken to their new positions, suffered nearly as much as those spring-planted, simply because they had not had time to root deeply. Where the moisture became exhausted from the immediate surface, they were in equal distress with those planted in spring. In pulling up some shrubs lately which were dead, or seemingly so, a rather curious appearance presented itself; the roots were bristling with young white growing points, showing that there was plenty of life there, although the knife showed by cutting the bark that the stems were dead to the surface of the soil. Those plants (*Cupressus Lawsoniana*) had been repeatedly watered, but had failed to keep the part above ground alive; evaporation had been so rapid throughout the heat and dryness of the day, and coldness and equal dryness at night, that the plant became exhausted in consequence: shade, therefore, in this case, would have been much more beneficial than watering, but for the practical difficulty of shading trees and shrubs by the acre. Exhaustion, I need not say, in a more or less aggravated form, was the general result, but in a very different degree on different subjects; whereas some plants became permanently paralysed, others only seemed to husband their energies and become exhausted in appearance only. Broad-leaved plants, such as *Rhododendrons*, American *Azaleas*, and the broad-leaved Japanese plants, suffered permanently, especially those subjected to the full blaze of the sun, and I believe more from actual heat than from drought; the thermometer at 100 and 120, with the sun blazing on them, actually had the same effect as fire, and the atmosphere heated to that extent would not have affected the plants in the same way had they been shaded. Almost the whole of the *Coniferae* stood the drought well, their wiry foliage being capable of withstanding a dry atmosphere. Now, since rain has fallen, however, recently planted subjects have grown well and made good roots. This is strikingly illustrated in the case of two specimen plants—*Thujaopsis dolabrata*—both of which had in winter occupied prominent positions temporarily for the purpose of decoration, from which they were removed in March. It was June when one of them became extremely dry at the root, while the other was even wet; both are equally fresh at top, but the dry one has made an enormous mass of fresh white roots, while the wet one had not made any. What has been the cause of this important difference? Was it the comparative warmth consequent on dryness that encouraged root-action, or the natural effort of the plant to obtain for its healthful existence moisture which the other enjoyed? The moist atmosphere of winter prevented exhaustion in the case of the dry tree. Probably *Coniferous* trees, as a whole, prefer a moist atmosphere and a moderately dry soil. Their natural habitats support this idea; the various forms of *Cupressus Lawsoniana* seem to stand drought the worst.

In the kitchen garden the heat and drought have had similar effects on vegetables. Broccoli, Cauliflower, and Cabbages showed exhaustion, in spite of much artificial watering. Onions, on the other hand, though they assumed that glaucous bluish-green which is the effect of drought, made good their hold in the soil, and when rain came made quite a rush into growth. Water in their case, under a scorching sun, would have been beneficial; but the Cabbage tribe, under strong sun, even with sufficient root moisture, make a flaccid and weakly growth. Herein lies the superiority of the north over the south in the matter of raising small fruits and succulent vegetables. A hot dry atmosphere will cause young Cauliflower to "bolt" and open their heads in spite of good cultivation, and Cabbage will refuse to make solid crisp hearts; but we in the south may fairly claim to know more about the cultivation of French Beans, Scarlet Runners, Tomatoes, and Vegetable Marrows, than growers in the north. Such a season as the past teaches us lessons which have been learned generations ago in Spain, where the value of irrigation is well known. All watering under such intense heat is useless unless thoroughly well done. This

I have been in a position to prove this season by having an abundant supply of water in some places and a scarcity in others. At one point I was able to allow water to run in a stream among some Roses, and their freshness and fineness of bloom formed a complete contrast with others not so treated. Moreover, these irrigated Roses have been completely free from blight, while others were hopelessly infested. I also irrigated a large portion of flower garden under bright sunshine with the best results. No garden can be called complete without a ramification of pipes and hydrants, and an abundant supply of water, which is procurable in the majority of gardens. Water is more particularly necessary in the fruit garden than in any other; for flowers and vegetables are too apt to get a full share of water at the expenso of fruit trees. Heat and dryness have a maturing effect on the wood of fruit trees when in conjunction with plenty of nourishment at the root; otherwise, they have a decidedly exhausting effect; and although wood may appear ripe, and abundance of fruit buds may have set—say on Peach trees—the following spring will most assuredly tell a tale of bud-dropping, fruit not setting, and disappointment at the stoning period; and the same remarks apply to fruit trees in general. Shade is a most important auxiliary in a variety of cases during a season of excessive heat, especially in the case of newly-planted trees and shrubs; while watering at the root will be found of no avail to keep plants alive, shade in some form or other will be quite successful. It obviates the scorching effects of the sun on a plant the cultivation of which has been impaired by removal. Materials for shading need not be expensive or difficult to get. Branches of Spruce or of common Laurel, even a handful of Grass or straw thrown over a plant, will shade it sufficiently to carry it through a trying time. The shade of trees to Grass enables it to retain its green appearance, while that exposed to the sun is scorched to the colour of hay. It is a bad practice to mow Grass too closely in times of heat and drought. Grass shades itself, and mulches the ground, and so prevents the sun from drying up the soil. Moreover, Grass condenses moisture, in the form of dew, for the maintenance of its own growth. Without Grass, dew is not deposited; therefore, lawns should not be too closely mown in very dry weather. All that is necessary for appearance is an even surface, which can be effected by adjusting the cutters of the machine by a sufficient depression of the front roller. Akin to shade is the benefit derived from the use of the syringe in the case of newly-planted shrubs and trees. Moistening the leaves and branches in the evening assists the leaves materially to maintain life. It may, sometimes, be possible to moisten a whole clump of shrubs or trees by a hose from a hydrant; or, when such is not attainable, a large garden engine and attendant water-barrel will effect much with the labour of two men. With several hundred feet of hose and a small hand fire-engine, we have been able to do good service among shrubs and trees lately planted. A dry spring and a heavy soil have taught us the lesson that the early autumn is the best time to transplant trees and shrubs, not excepting Hollies and Conifers. There is one class of plants that shows wonderful tenacity of life under heat and drought—namely, Mosses and Lichens. No plant seems to enjoy moisture more than they do, even to saturation, when they grow with wonderful rapidity, yet none stand draught better. The sun does not seem to have the power of killing many of them, even on stones that become so hot that one cannot bear the heat with the hand. Even some Ferns bear dryness with impunity. Large masses of the common Polypody may be seen perfectly dried up; to all appearance the fronds are gone, yet, with the first rain it springs into a mass of verdure.—*The Gardener.*

Lord Palmerston on Iron Railings in the Parks.—"91, Piccadilly, Nov. 12, 1857.—My dear Hall,—I have been much surprised this morning at seeing a party of labourers employed in trenching a large piece of the Green Park. As head of the Government I have a right to expect that essential alterations should not be made in the spaces allotted for the enjoyment and recreation of the public without my previous sanction and concurrence, and I entirely disapprove of the restrictions which you are imposing upon the free enjoyment of the Green Park and Hyde Park by the public. Your iron hurdles are an intolerable nuisance, and I trust that you mean shortly to remove them. To cut up the Green Park into enclosed shrubberies and plantations would be materially to interfere with the enjoyment and free recreation of the public; and I must positively forbid the prosecution of any such scheme. As head of the Government, I should be held by the public to have authorised these arrangements, and I do not choose to be responsible for things which I disapprove.—Yours sincerely, PALMERSTON. Right Hon. Sir Benjamin Hall, Bart." The above, from the "Life of Viscount Palmerston," does not appear to have had all the effect that could be desired in modifying the too numerous and ugly iron railings in our parks.

MR. LEY'S NURSERY, CROYDON.

This nursery, though comparatively newly formed, has already become interesting to the plant-lover. An elegant conservatory (of which the annexed is a representation, engraved for THE GARDEN from a photograph) has just been erected in it by Mr. Lascelles, and is remarkable as proving that it is possible to have horticultural buildings made of wood as light and graceful as any constructed of iron. Hitherto it has been supposed that to have curvilinear houses we must resort to iron. Mr. Lascelles now builds them for us in wood, having as easy lines as the fine iron curvilinear houses built by Mr. Turner, of Dublin. This seems to us to effect a revolution in the art of hothouse building, and a very desirable revolution, too. The curved wooden spandrils of the roof consist each of three pieces, bent by steam, and very accurately fitted together. Although, however, the spandrils are bent, the glass is not; and in this there is a decided advantage, inasmuch as a difficulty is often experienced in replacing broken squares when such is the case. The interior is divided into three compartments, which afford plenty of space, not only for plants of comparatively small size, but also for the larger forms of tropical vegetation.

Palms.

One thing worthy of mention here, is the fine collection of Palms, numbering upwards of 170 species, all in a healthy thriving state, and well adapted for the general purposes of indoor decoration. Here are thousands of individual plants in all the different stages of development, from the seedling state to splendid well-developed specimens, and we are glad to see that Mr. Ley attaches so much importance to this noble family, which seem destined to become even more popular and useful than at present. In the different houses we were shown from 10,000 to 12,000 seedling Palms, such as *Seaforthia elegans*, *Areca rubra*, *A. lutescens*, *Corypha australis*, and many others of well-known excellence as decorative plants. Among the rarer kinds we may note *Cocos plumosa*, *C. Weddelliana*, one of the most graceful and effective of all decorative plants for the dinner table, *Dæmonorops fissus*, *D. plumosus*, *D. palembanicus*, and others equally graceful. Among the newer kinds, *Cocos Maximilliana* deserves mention as a graceful species, somewhat resembling *C. plumosa* in general habit. *Phycosperma Alexandre* may be described as a silvery-leaved form of *Seaforthia elegans* from Lord Howe's Island, and is a plant likely to meet with general culture when fully developed and better known. One of the finest specimens in the whole collection, however, is *Chamærops tomentosa*, one of the most graceful forms in the genus, the slender divisions of the fan-shaped leaves being covered below with a dense silvery tomentum, which gives it a very distinct and pleasing appearance. This plant is fully 8 feet in diameter, and is one of the finest of all decorative Palms, either for indoor decoration or for exhibition. A fine healthy plant of *Chamædorea Hartwegii*, bears a great panicle of rich orange-scarlet fruits as large as Peas, and when in this state it forms a very ornamental plant. All the *Chamædoreas* are beautiful, especially when in a young state, from 2 to 3 feet in height, while their coral or ivory-like panicles of bright berry-like fruit render them peculiarly beautiful and distinct from nearly all other slender Palms; even when not in fruit they are graceful fresh green plants, and many kinds are valuable for the decoration of apartments, as they will succeed in a moderate temperature.

Ferns.

These graceful plants are quite a speciality here, and the collection, besides including those most generally grown for decorative purposes, also includes many rare and interesting species rarely met with, except in the best public gardens. The collection generally is a very select one, containing a large stock of healthy plants of such species as *Adiantum Farleyense*, of which alone we saw at least two hundred fresh little specimens; *Adiantum sulphurum* is another pretty little novelty, the stock of which Mr. Ley was fortunate in raising from spores two or three years ago. This is commonly known as the Golden Maiden-hair, and when well grown is one of the most delicately beautiful plants in the genus. Another old favourite is the deciduous *Adiantum lunulatum*, which does remarkably

well here, producing fresh green fronds from a foot to nearly 18 inches in length; *Todeas* and *Hymenophyllum* grow well; and a very distinct *Selaginella*, named *S. californica*, is a very interesting addition to the genus. In habit it may be described as resembling *S. caulescens*, but the growth is much more robust, of a deep glossy-green colour, and the broad scales are imbricated closely, just like the scales on a snake's back. This will be much liked by cultivators of *Lycopods*. A new *Lycopodium*, with umbrella-like tiers of fresh green growth, is very distinct in habit from anything we have seen. This has only recently been introduced, and is only an inch or two in height, but it shows signs of being well worth general culture as a decorative plant. Among many choice *Adiantums* we noted *A. sentum*, *A. caudatum*, *A. decorum*, *A. amabile*, *A. cardiophyllum*, *A. rubellum*, and others, as well as the fresh

beautiful *A. Victoriae*, grow luxuriantly, forming charming tufts of gently-arching fronds of the freshest green tint imaginable. Great tufts and masses of the Oak Fern (*Polypodium dryopteris*) also do well here, together with the pretty little *Lomaria alpina*, *Cystopteris fragilis*, and a great many North American *Osmundas*, such as *O. cinnamomea*, *O. gracilis*, *O. cristata*, *O. Claytoniana*, and other Ferns. Mr. Ley imports many hardy Ferns from America, and, in addition to the *Osmundas*, we may note the charming *Adiantum pedatum*, some pots of which would bear comparison with any other exotic species, for graceful beauty and vivid freshness. The rockery above referred to is sheltered and shaded by a belt of Poplars and Weeping Willows, which form a cool and shady retreat during the hottest of the summer weather. The rock-work itself is artistically formed of cement, on a ground-work of

Curvilinear Wooden Conservatory in Mr. Ley's Nursery, Croydon (erected by Mr. Lascelles).

green *Asplenium formosum*, and *A. Fernandezianum*, all rare and beautiful Ferns, well worth culture. In one of the houses here we were shown a rather novel method of propagating hardy Ferns by cutting the fronds, a system by which it is possible to increase the stock of new and rare varieties in a comparatively short time, as compared with the older method of propagating by division. The kinds so treated were *Scelopendrium*s and *Polystichum*s, and we were assured that fifty percent. of these frond-cuttings root freely and form plants. Hardy Ferns are grown in quantity, and some of these are really little less beautiful than their tropical representatives. Mr. Ley has constructed a shady rock-work for hardy Alpines, Ferns, and herbaceous plants, extending along one side of his Lansdowne Road establishment, and many of the beautiful forms of *Athyrium filix-femina*, such as *plumosum*, and the

stones and clinkers, and the general effect is as natural and excellent as the limited space at command will allow. This rock-work, enlivened by the pleasing sound of trickling water, forming as it does a cosy sheltered retreat, and an excellent position for the culture of Ferns and other choice shade and moisture-loving plants, shows us what can be done in hundreds of little town and suburban gardens; while the result attained, although perhaps a trifle more costly in the first instance, is far more satisfying than the everlasting strip of turf, cut up into intricate designs, and intersected by walks leading from everywhere in general to nowhere in particular. Gardens, small ones more especially, where expense is an object, should be so laid out, that they cost but little to keep them in order, and they ought to increase in beauty every year. This can never be the case where complicated designs are carried out,

and a host of bedding plants are required every season. Mr. Ley has rather a novel method of growing *Stephanotis floribunda*, which simply consists in pruning in the young growth like a Vine, after which the long shoots are brought outside the house through a hole in the wall, and trained out at the end or side fully exposed to the sun and air. Thus treated the growth becomes thoroughly hardened or ripened, and after the plant is trained inside the house again in the autumn, an immense crop of flowers is the result. This is a most excellent plan to adopt in order to secure a succession of its pearly-white sweet-scented flowers late in the season, and, at the same time, the plant is kept free from mealy bug, brown scale, and other insect pests, with which it is so often infested when grown inside the house in the ordinary way. Some very fine specimens of *Eucharis amazonica* were also turned out-of-doors to rest. These plants were, however, not allowed to become dry at the root, but simply turned out into the light and air, so that their bulbs might "plump up" and become thoroughly well ripened; so treated, Mr. Ley finds nearly every bulb to throw up a strong flower-spike soon after they are removed to more genial quarters, the result being a profusion of sweetly-perfumed snowy-white flowers, at a season of the year when they are most required, and when they fetch the best price in the market. B.

MR. MEEHAN ON THE ORIGIN OF NEW PLANTS.

In any theory of evolution, morphology must play an essential part. In the transformation of a leaf blade to the various organs of a plant the change is sometimes gradual, as in the passage from leaves to bracts in some orders, or from sepals to petals, petals to stamens, or stamens to pistils in others; but the cases where the change is from one form of structure to another of very different character is by no means rare, and if it can be proved that change with gradual modification and change by the sudden appearance of a distinct form are both good morphological laws in plant life, there is no reason why both laws may not operate in any scheme in which morphology is called to act. How suddenly the parts of plants often change is well illustrated in most Coniferous plants. The Pines, on the first pushing of the axis from the Cotyledonous condition of the plant, flat leaves are developed often an inch or more in length. After some time these leaves are suddenly arrested, and the axillary buds as suddenly develop into fascicles of needles, as they are popularly called. So when the plant reaches its floral condition, the transformation of leaf and stem into the various parts which constitute a cone comes on with wonderful suddenness. The leaf which we saw so suddenly arrested in early life now becomes a bract, the fascicle combine and form the scale, and the axis suddenly ceases to elongate and gives form to the whole. The one in search of missing links would be sadly puzzled here! This sudden change of folial organs to organs of inflorescence is very common. In the change of one portion of a leaf structure to another, *Magnolia* and *Liriodendron* afford an interesting example. In many plants the regular leaf-blade is metamorphosed, and forms the petal, but in these, as soon as the plant reaches its flowering stage, the leaf-blade is suddenly and entirely arrested in the formation of the petals, and the stipules are as suddenly developed. The petals are, in fact, highly developed and transformed stipules, and all without the slightest trace of gradual modification. So in sexual transformations the modifications are by no means always gradual. One who had never seen the Maize growing would hardly believe the tassel and the ear were from one plant, yet they are formed morphologically on the same plan, and once in a while we find male flowers gradually merging into female, and females to males in the respective domain of each, but this is the great exception to the general rule. Now we come to variations from specific form, and here I find great changes with no transitional forms between. I have a *Halesia* from seed of *Halesia tetraptera*, which anyone might be pardoned for placing in a new genus. It is much further removed from its parent than *H. diptera* is. The corolla is not drawn up into a funnel-like tube as in the original, but is cupular and barely the length of the stamens. The leaves are broadly ovate and rugose, and no one at first glance would take it for a *Halesia*. When I first saw it in the seed bed I supposed it to be a young Apple tree. I have on my grounds large quantities of *Yucca filamentosa*. Hundreds of plants throw up their flower spikes and open their first blossoms within twenty-four hours of each other. But some years ago one struck off to have a more branching panicle and to open its flowers two weeks before the others, which characters remain and are continued in the progeny. This two weeks was not gained gradually, day by day, through successive generations, but in

one great leap. So with raising Peaches or other varieties of fruit. Though the progeny usually take to the general habits of the parent, there will be, once in a while, very late varieties from seeds of early ones, and very early from late kinds. In Delaware and New Jersey *Azalea viscosa* varies to a form having glaucous saliciform leaves. I have not raised these up from the seeds, but I have seen an extreme form, with leaves looking rather like the English Woodbine than an ordinary *Azalea viscosa* growing under ordinary circumstances, which left no doubt on my mind that it sprang without any intermediate links from the other form. *Glyptostrobilus* is another remarkable case. I exhibited branches from a tree raised from seed of *Taxodium distichum* and branches from an acknowledged *Glyptostrobilus pendulus*, and no one could separate them. Here is a leap at once to a new genus. Moreover, I have a *Thuja* growing, which the highest authorities insist is a *Retinospora*, but which I know was raised direct from the *Thuja occidentalis*, without any intermediate parent whatever. Some genera seem very variable. Take our common Ox-eye Daisy for instance, and then, say in *Staphylea*, we may examine hundreds of plants without any apparent variation. But in the variable genera it is a mistake to suppose that these variations are by gradual modifications, though one can often place them so as to appear like gradually-approaching links. It is wonderful how many variations there are in the common Ox-eye Daisy. I have studied them closely for years, and find that the most divergent forms are often parent and child. I do not know anything that more exactly repeats itself than *Glycine frutescens*. Every leaf is exactly ovate, with an upward turn from the mid-rib; but in its variety, known in gardens as *G. magnifica*, the leaves are regularly attenuated and reflexed, and the whole manner so different, that some have supposed it a distinct species, with the name as above. Not only do strikingly distinct forms come suddenly into existence; but, once born, they reproduce themselves from seed, and act in every way as acknowledged species. The Peach in its general form has its branches at a very acute angle upwards; I never saw a plant with branches approaching a right angle; but some thirty years ago one came into existence with a strong angle downwards, a weeping variety, and seeds of this reproduce this form exactly in every respect. So with colour. The Peach is of an uniform green—no tendency to vary its shade—but ten years ago, a deep blood-leaved variety appeared. The deep blood-leaved Peach is also a rapid jump from the green, and reproduces the blood-leaved character from seeds. The Siberian Arbor-Vitæ is another great leap from the *Thuja occidentalis*, and reproduces itself from seeds, as do all the striking forms in which this species abounds. Indeed, I think, I may close this branch of my subject by the statement that in over a quarter of a century of experience among living plants, I have rarely known any striking form to have originated by gradual modifications, but always by one great leap. The slight changes are generally in efforts backwards, as when we sow purple Beech seed some few are a trifle paler than their parents—there is little of this hesitation in the forward leap. But even reversions are not always gradual. Some years ago the common Babylonian Willow sent out branches suddenly which bore singularly curved leaves, just as the Nectarine is said to have suddenly sprung from the Peach. The cuttings grew and maintained the character. It is known as *Salix Babylonia annularis*. A few years ago I saw a tree, perhaps twenty-five years old, push out the regular Weeping Willow leaves. This fact in regard to the Willow suggests another great principle. Forms are not only called into existence suddenly, widely different from parents, and can reproduce themselves from seed, but they come into existence without seed agency, and the same or similar form in widely-separated localities, and not all necessarily by seed from one individual. I have had sent me from five different localities, flowers of *Viola pedata* in which the two upper petals were of the beautiful maroon characteristic of the Pansy. Again a whole change of character will occur suddenly in many individuals through a large extent of country. This season, in our part of the world at least, half the leaves of the *Liriodendron* are from five to seven lobed; when, as it is well known, the three-lobed character has been almost specific in former years. We are accustomed to say about these changes that they are "caused by climate;" but this expression proves nothing. We have in Pennsylvania a form of *Viola cucullata*, usually growing in wet places, which always causes the breast of the young botanist to thrill with the idea that he has a new species. The paler colour and more delicate growth, when the plants are seen in the aggregate, are very striking. But when the plants and flowers are analyzed, no difference is found that can be described in words. A review of the facts I have presented shows, I believe, the following truths:—1. Morphological changes in individual plants are not always by gradual modifications.—2. Variations from specific forms follow the same law.—3. Variations are often sudden, and of such decided character as to be deemed generic.—4. These sudden

formations perpetuate themselves, and act in all respects the same, as forms which spring through gradual modifications.—5. Variations of similar character occur in widely separate locations.—6. Variations occur in communities of plants simultaneously by causes affecting nutrition and perhaps by other causes. Arguing from these, now and widely distinct species may be suddenly evolved from pre-existing forms without the intervention of connecting links.

THE ENGLISH IN THE NATURAL PARKS OF COLORADO.

We lately spent two delightful days in Bergun's Park, which beautiful retreat lies about 1,000 feet higher than Manitou, and is reached by a charming drive of 17 or 18 miles up the wild Ute Pass. We were the guests of Mr. Thornton, an English gentleman of good family, and a graduate of Cambridge, but quite content with this rough secluded life, and proud to be a ranchman. The English younger sons who do not go into the Church or the army come to Colorado. Well may this particular ranchman be proud; for the ranch which he owns, in partnership with his friend, Dr. Bell, is fit for a royal domain. It is royally grand and beautiful, and, though so high up, is largely under cultivation, yielding the best of Wheat, Oats, Barley, and all varieties of vegetables, while for grazing purposes it is unsurpassed. Nothing can be lovelier, more still and peaceful, than this magnificent ranch, lapped on the mountain slopes, and set about with primeval Pine forests. Through it runs a clear trout stream, fringed with Willows, and low-lying meadows and uplands are almost alike green and flowery. It is a vast amphitheatre—mostly wild, of course, yet has a strangely pastoral and home-like aspect. It reminds one of the "Happy Valley of Rasselas" in its sublime seclusion. The scene has all the purity of atmosphere, all the sombre inspiration of the mountain; all the tranquility and coziness of the valley land. We found the brilliant noon-day hot, even here, but the nights were deliciously cool and balmy. Bergun's Park contains some of those curious and imposing monumental rocks of red sandstone which are such a marked feature in all this region. They are of a peculiarly weird character, and full of grotesque forms and faces, such as we find about old cathedrals. Indeed, some one has named the largest of them "the devil's minsters." Though the ranch is apparently closed in, except on the side of the great pass, down which you look till Pike's Peak seems to block the way, and to compel the morning to climb over him, a ride or drive of a few miles brings one to mountain points whence views of surpassing loveliness and grandeur can be obtained. Mr. Thornton has within the past year erected a new ranch-house, roomy and pleasant, with open fireplace as spacious as the one in that grand old feudal hall of Warwick Castle, and also three cottages for visitors. One of these, however, is designed for private use during a portion of the year, being the forest lodge of a wealthy English lady. It is a marvel of rustic comfort and picturesqueness. This was assigned to us, and we had rare delight in it. Each evening, after watching out the sunset, which paid its last salute to Pike's Peak, we left the pleasant verandah for the large sitting-room or hall, where we gathered about a flaming fragrant, open fire, and told stories and "laughed at little jests," and, in short, were happy and glorious, with the larger part of the human race far below us. It is good to get above the world. I cannot too highly recommend this charming mountain retreat to invalids who can do without, and ought to do without, the excitements of a fashionable watering place; to mothers with delicate children; to students who can take with them the goodly company of books; to artists, seeking quiet studies; and to sportsmen eager for deer-stalking and bear-hunting. There are no wild creatures on the settled part of the ranch, but off on the mountain sides and at certain points on the creek, where they come to drink, by cautious hunting you will always find them. Sometimes they find you. To fully enjoy Bergun's Park, visitors should take saddle-horses, in order to explore in all directions the fragrant forests of Spruce and Pine—almost as clear of unsightly brush and undergrowth as English woodlands. But they also thrive who only rest and eat. The ranch-house table boasts delightful English cooking—light, snowy bread, delicious butter, juicy beef, tender mutton, game in season, fresh eggs and vegetables, abundance of milk and rich cream, such as the lower world has forgotten since it has gone up so. And, to crown all, the prices of board, with lodging, in those royal log cottages, are much lower than at lower hotels. I hope that another season a host of happy tourists will find out for themselves this mountain haunt of loveliness and health—this darling retreat of Nature, so far and so fair—this glorious little epitome of Colorado. [The above description by Grace Greenwood, in the *New York Times*, must be understood to refer to an oasis in the far from attractive deserts of the "Great West."]

THE KITCHEN GARDEN.

POTATO CROPS IN WORCESTERSHIRE.

WITH an unusually dry summer up to September, we have been enabled to harvest our crops of early and second early Potatoes, that were planted early in the season, in the best possible condition, and perfectly free from disease. Previous to the occurrence of rain I had not discerned a single trace of blight; and even late sorts, now that the season is so far advanced, and the tubers maturing rapidly, may be expected to produce a full average yield, notwithstanding that, with the advent of rain, disease manifested itself in its usual form. Tender sorts are now suffering severely from it, and there cannot be a doubt that, with increasing moisture in the soil and increased atmospheric humidity, the infection will spread rapidly. I would, therefore, suggest that no opportunity be now lost in lifting and harvesting. More particularly is this to be recommended as the tubers are making a second growth actively, and, in some instances, super-tuberating, which will quickly and materially deteriorate their quality. Notwithstanding all that has been said and written respecting the disease we have not yet discovered any certain cure for it. Previous to the great failure in 1815, no particular mode of cultivation was practised; ordinary field Potatoes were planted generally in drills upon the grossest of manures, and generally with the best results. Now we find that such manures applied at planting time, more particularly in the case of late kinds, are apt to favour the disease, and, therefore, should always be avoided, as should also land that is rich in humus. A fresh soil suits Potatoes best, and the manure should always be applied months previous to planting, incorporating it thoroughly with the soil. Lime is also an excellent fertiliser for this crop; and early planting cannot too often be recommended, as it favours early maturation and facilitates early lifting, thus avoiding, as much as possible, the autumnal rains which so much encourage disease; for in dry weather it makes but slow progress. We hear from time to time that certain kinds are "disease proof," but, if so, I have never yet seen them. Certain coarse-growing sorts with hardy constitutions, however, withstand the disease better than others, as, for instance, the Rough Red, &c., but these semi-disease resisting varieties are, for the most part, poor in quality, and not to be compared with such standard sorts as Victoria, Spencer's King of Flukes (an excellent sort), Carter's Main Crop, Red-shinned Flour-ball, which is good upon some soils, and beautifully white when mashed, also a great cropper; King of the Potatoes, a good and prolific variety of fine and even size; and the various sorts of Regents, which are all of good quality. As we are powerless, both in evading and stamping out the disease, it behoves us to select varieties of good quality with strong constitutions, and to plant them early upon thoroughly drained well prepared soils, in order, as much as possible, to encourage early maturity, on which, as I have said, success in Potato growing mainly depends. GEO. WESLAND.

The Gardens, Witley Court, Sturport.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Sawdust a Better Plunging Material than Tan.—For some years I have used sawdust extensively for plunging Pines in, and nothing can be more satisfactory than it is, the heat being lasting and genial, while the actual work in plunging a pit of Pines is not only pleasant but in appearance superior to that of tan or leaves. I have a vivid recollection of the condition of my poor trowser's-knees when plunging Pines among fresh tan.—R. GILBERT, *Barghelly.*

The Hertfordshire Dwarf Cauliflower.—I have tried a great many sorts of Cauliflower, but have found none to equal this and Veitch's Autumn Giant, two kinds which have withstood the late dry summer so well that, for the future, I have made up my mind to grow no others. The Hertfordshire Dwarf is especially excellent, and I would recommend those who wish to have a good Cauliflower all through the season to give it a trial.—RICHARD NISBET, *Asenbury Park, Falmington.*

Clubbing.—Large numbers of the Cabbage tribe in Berry Grove Gardens have clubbed this season; Mr. Bridger, therefore, took up the plants, cut off the affected portions of the roots, and replanted. All thus treated, with one exception, have grown into fine healthy plants. Is this mode of treatment generally practised? It was new to me, for I had invariably seen Cabbages and Broccoli that had clubbed taken up by our gardener and thrown away.—HELEN E. WATNEY.

Flue-heated Cucumber Pit.—I have a pit 6 feet wide and 33 feet long. Its back wall is 9 feet in height, and the front one 2 feet 6 inches. The bed is 1 foot wide; the path 2 feet, with ventilation at back and front. Will you instruct me as to the best method of heating this by means of a flue, so that I may cut Cucumbers from April to the end of October?—(L. FOKS. [A house or pit of the width just given cannot be heated by a flue with safety otherwise than along the back wall. To increase the heating surface, the fire-place should be at one end of the house, and sunk deep enough to permit the bottom flue being carried along in the back wall, about 1 foot or 18 inches above the path level, to the other end of the house; and it should return again by another flue, just above the bottom one, to the fire-place, above which the chimney should be placed. The flues must be square, not round, and immediately above the top flue the wall should be pigeon-holed, which will greatly increase the heating power. Any intelligent bricklayer understands how to make such a flue. If the house is heated in this way, there will be no difficulty in keeping up sufficient heat for Cucumbers for six or eight months in the year.—J. S. W.]

THE GARDEN IN THE HOUSE.

BUTTON-HOLE BOUQUETS AND COAT FLOWERS.

Few seem to understand that there is any difference between a button-hole bouquet and a coat flower; yet there is, and a very great difference too, the flower being, as the word signifies, a single bloom, whereas a bouquet means a number of flowers arranged according to taste. Many opinions have been expressed as to the proper arrangement of cut flowers, but, with a few exceptions, button-hole bouquets have been excluded, probably, because being small, people have imagined that they must necessarily be easily made. No combination of flowers, however, requires to be put together with more taste, or to be more lightly done, than a properly made button-hole bouquet. Flowers selected for this purpose should always be good, particularly those for mounting singly, which should, in fact, be specimens of whatever kind is chosen. Ferns, I always like to see in such bouquets, and also along with coat flowers, provided these are stove or greenhouse kinds; but hardy flowers I like best mounted with their own own foliage alone. Nearly all flowers for bouquets of any sort should be wired; indeed, many could not be used for that purpose at all were they not mounted on wire, as for example, the pips of white Hyacinths, which in winter are amongst the most useful flowers that we have. There are, however, other ways of mounting flowers besides wiring them. Let us take, for example, a Gardenia. The centre petals of this flower—indeed, all except the outside row—are very even and lovely; but their beauty is somewhat marred by the outer ones, which look twisted. Now, to remedy this evil, and to make them look all even, proceed as follows:—Take a common Laurel leaf, and cut a piece out of it, about an inch or so square, with a pair of scissors; trim round the corners, so as to make it almost circular; then cut a cross in the middle, and down through that push the stem of the Gardenia, until the flower and the Laurel-leaf are pressed tightly together; then hold it upside down, and through the stem, close to the leaf, pass a “stub” wire (which will keep the leaf in its place); bend the ends down, and fasten them together with a little binding wire, so as to form a stem. The petals of the flower can be then arranged so as to occupy their proper places, and, the piece of Laurel-leaf being so tight to the flower, they will remain wherever they are placed. There is also another point to which I would wish to direct attention, and that is the foundation of the button-hole bouquet, which is generally a piece of Maiden-hair Fern; but that is not stiff enough in itself to form a good support for the other flowers. To remedy this, the best plan is to back the Fern with a small Camellia-leaf, wired, which will keep the whole bouquet firm and in shape. The following arrangement is that generally adopted: at the back is a spray of Fern; next, some long light flower, so as to form a kind of point or finish at the top; then a Camellia bud or Rose, or some such flower, and then Maiden-hair Fern and whatever other small flowers are at hand. A bouquet, to look well, may consist of a white Camellia bud, some sprays of Lily-of-the-Valley, blue Squills, &c., and Maiden-hair Fern. I once made one of a half-open white Camellia bud, a spray of *Hoteia* (*Spiraea*) japonica, and a few pips of white Hyacinth, mixed with a little Maiden-hair Fern, and many remarked that it was very light and elegant. That which took the first prize at the Royal Horticultural Society's Show at Birmingham, in 1872, was composed of a yellow Rose bud associated with blue Forget-me-not, a pip of *Kalosanthes coccinea*, and one of white *Bouvardia*. I have seen one made of Lily-of-the-Valley, a blush-coloured Rose bud, and the same shade of Hyacinth pips, with a little Fern worked through it; this was a neat-looking little bouquet. Another consisted of a spray of Lily-of-the-Valley, a yellow Rose bud, and a few pips of a rich purple *Cineraria*, which came out well against the deep colour of the *Maréchal Niel* bud. I could give descriptions of many others, but think that those which I have mentioned will suffice to show the best shape and style in which such bouquets should be made. Ferns used for button-hole or, indeed, for any kind of bouquets, should be cut off plants that have been grown in a cool house or that have, at all events, been well hardened off;

otherwise, though they may look nice and fresh when cut, they shrivel up in a few hours, when, of course, their beauty is gone. In the case of Maiden-hair, it is a good plan to cut off the very young points, as, with the exception of these, the other parts of the frond keep well. Another point that should be remembered, is always to keep the stems of the bouquets as thin as possible, in order that they may easily pass through the coat, and nicely fit the little glass water-tubes which are now so much worn, and which keep both Ferns and flowers fresh so much longer than they otherwise would be. After the bouquets are made, many place their stems in water, to keep them fresh; this I do not think a good plan, as, though the stems may be in the water, the Ferns are exposed to the air, and, thus circumstanced, they will not keep nearly so long fresh as if they were shut up in some air-tight box or drawer. Dealers in bouquets have numbers of drawers lined with zinc in which they keep their flowers, mounted or otherwise; those who have shops must have such appliances as these, but it is not to be expected that amateurs will be furnished with them. If I want to keep a coat flower from one day to another, I place it in a common tin box with a tight-fitting lid, such as wafer biscuits are sold in, over the bottom of which is laid some wet Moss of the kind one gets in bundles at the flower shops, or finds in woods or on banks. I place the back of the bouquet next the Moss, and cover the stem over with some more wet Moss; I then sprinkle the flowers and Ferns well with water, and then shut down the lid, which is as air-tight as possible, and, treated thus, flowers and Ferns will keep fresh for days. If I want to send a bouquet by post, I put Moss enough in the box to raise the bouquet, when laid on it, nearly level with the lid when shut down; and across the face of the flowers I lay a piece of cotton wool, which keeps them from rubbing against the lid.

Coat flowers I like associated with fronds of Maiden-hair Ferns, that is if the flower is an indoor one, as what, for instance, looks so elegant with a Gardenia as a bit of *Adiantum cuneatum*, the bright green spray of which sets off white blossoms of all kinds to much advantage. The coat flower to which was awarded the second prize at the Birmingham show before-mentioned, consisted of a small spray of red *Combretum* backed with a frond of Maiden-hair. There are numbers of flowers suitable for such an arrangement as this, but care should be taken that such as are selected are good specimens of their respective kinds, and be a little shrouded in the Fern, as many coat flowers I have seen were quite spoiled by having only one spray of Fern, against which was laid the flower; the latter, under such circumstances looking hard and stiff. Now, had there been another small piece to fill up the space at the base, and a tiny bit drawn across the flower, the effect would have been much enhanced. This should always be done if the flower used is of a bright or glaring colour. I always like to see a Rose with a leaf belonging to itself behind it, and a few sprays of the young brown-coloured growth around it. Such an arrangement may seem easy to manage, but this is not the case, as the Rose-leaf must be wired, and that is one of the most difficult of all things to do properly. Take a Rose leaf, and lay it face downwards on a table. It will then represent a stem with two or three small leaflets on each side and one at the top. Down the centre of each of these small leaves or leaflets is a comparatively thick mid-rib, with slighter ones branching off from it. Take a piece of fine wire and pass it through the leaf (always selecting the top leaflet first), under one of these slight ribs, and bring it up on the opposite side of the ribs. Subject two or three of the ribs to this operation, always keeping close to the centre rib: in fact work as if you were sewing through the leaf, having the long stitches, if I may so call them, on the wrong side, and it will take great care and practice to keep them from being seen on the right side. The wire should be cut off at the top, so as not to let it appear above the point of the leaf. The other part should be drawn down the long stem, and given a twist here and there; but take care to keep the wire from being visible. The little side leaves should be done in the same manner, the only difference being that the wire is cut off at each end, and not brought down the long stem like the top one. To do all this well takes some little time and trouble; but a Rose leaf if not mounted as just described, is liable to get

out of shape, and to hang down; if wired, however, it keeps stiff and can be bent back and arranged according to fancy, just as one would adjust an artificial leaf. It has lately come into fashion for ladies to wear small bouquets in the front of their dresses or jackets. These are similar in every way to those just described, except that they are at least a full size larger; the directions therefore given for mounting ordinary button-hole bouquets, will suffice for those worn by ladies.

A. HASSARD.

A LIVING VASE.

THIS process of ornamenting vases is by no means new; but, as the thing is still far from being common, and as it may conduce to other analogous applications, we have deemed it worth while to give a representation of it so as to show the result, and to indicate the means employed to obtain it, which are most simple. Though any kind of vases can be used indiscriminately, those in unglazed terra-cotta are preferable, being porous. In such vessels the water with which the vase is filled percolates constantly through the sides and moistens the plants which are fixed on its surface. This kind of vase is, however, not indispensable, for we can ornament all kinds, whether in glass or metal. In the latter case it is necessary to prepare the surface so as to convert it into a sort of soil, which it

A Coop of Cress on a Vase.

really represents—an operation which is easily managed by the aid of a piece of cloth or lannel which is fixed by means of a little pack-thread or thin iron or brass wire. This being understood, the means employed to grow the seed must next be described. If a porous vase be used it is filled with water or, better still, left in a pail of water to soak. After the lapse of twenty-four hours, when the water has thoroughly saturated the vase, it is laid on its side, and the seed sprinkled slightly over the surface, taking care to turn the vase in different directions, in order that the whole surface may be well covered with seed. This operation terminated, the vase is placed in a dark closet for some time, and, if possible, under a glass frame, so as to preserve humidity and facilitate germination. When the plants are developed, and in case they get detached from the vase, they are secured by passing round, in different directions, a little packthread or fine wire, which soon disappears under the vegetation. If a non-porous vase, after having well soaked the cloth which covers it, the seed is sown upon it, and the same care is given it as has already been indicated. When a porous vase is used it should be kept constantly full, as it is the water filtering slowly through it that feeds the plants which cover the sides. If that be insufficient to ensure vigorous growth, the vase must be watered, taking care to pour the water cautiously, so as not to detach the plants. If glazed or metal vases be used, glass bottles for instance, they must be constantly watered; the water should be poured from the top over all, so that, in descending, it wets all parts of the cloth, which should always be damp. Whenever the plants droop they must be refreshed by watering them carefully. The vase should stand in a saucer or plate. The seeds used should be very fine, and especially light and of easy and quick germi-

nation. The common Garden Cress is most suitable from its great rapidity of growth, the easy and very quick germination of its seeds, and also on account of the little nourishment the plants require; but it has several drawbacks: first, it has a tendency to sink more or less, then to leave gaps, to show flowers very quickly, and then to wither away. The common Ryegrass is also suitable, but experiments with other seeds may be made. We ought to multiply and vary the experiments until satisfactory results are obtained. The following kinds of plants might prove suitable:—Crested Dog's-tail Grass, White Clover, Yellow Clover (*Medicago lupulina*), Flax, but particularly the Timothy Grass (*Phleum pratense*), which appears to be singularly appropriate for this mode of ornamentation.—E. A. CARRIERE, *Revue Horticole*.

THE ARBORETUM.

THE BEST CONIFERS FOR BRITAIN.

I HAVE read with interest "A. M.'s" article, in last week's GARDEN, on this subject, and I think it will be of great use to future planters. There is only one statement in it which is, I think, open to question, and that is that the Deodar will be a good substitute for the Larch. Within the last fourteen years we have had two frosts, that of 1860, which, to my own knowledge, destroyed many Deodars, and more or less injured all others in this neighbourhood; and that of 1867, which destroyed several Deodars at places that I could name in different parts of Surrey. I only name these two places as having come under my own experience, but I am convinced that the same thing has happened in other parts of England. I have not seen the Deodars at Riccarton for some years, but must own that when I did see them they did not look as if they had ever suffered or been retarded in growth by frost; but I cannot help fearing that some day or other a severe frost, coming, perhaps, after an exceptionally wet summer, may play the same havoc among them that has already been played amongst those in other parts of Britain. I must, therefore, beg to differ from "A. M." in thinking that a tree which has twice in the last fourteen years suffered so severely from frost can be recommended for planting on an extensive scale. The Douglas Fir, on the other hand, seems not only able to stand any amount of frost, but any amount of drought as well, as in a small mixed plantation of three years' growth, on a gravelly hill in this neighbourhood, it is now almost the only survivor of this almost unparalleled season of drought.

A NOTTS. READER.

RETINOSPORAS IN POTS AT KEW.

How is it these beautiful Conifers are not oftener met with than they are? Their scarcity cannot be attributed to their not succeeding in our fickle climate, for they seem as much at home with us as the Spruce or Silver Fir. They are, indeed, as hardy as a Stone Pine; they are the best of all Conifers for villa gardens; they need no house in which to grow them, much less pots. If I were asked why we do not find them growing abundantly in all gardens, I should be inclined to answer that we cannot expect people who see stunted, half-starved, deformed scrubby trees growing in huge costly glass buildings, such as the temperate house at Kew, to have the most remote idea of planting them out as hardy subjects, even should they be of an attractive character, which is more than can be said of the Retinosporas at Kew; nay, it is a gross injustice to this beautiful family of hardy Conifers to keep them in the plight in which I saw them there last spring. Surely, if Retinosporas are worth growing at all, they are worth growing well. If scarcity of room is pleaded, I would do away with a few plants of *Araucaria Bidwillii*, and one or two other things that so frequently crop up there. If Retinosporas really must be kept in this fine house at Kew, why not devote a bed to them in which they would grow and show themselves to advantage? Than such a bed nothing would be more admired, if we may judge from what we have seen when a good collection of them have been met with outdoors. But why grow them indoors at Kew? I have seen really well-grown specimens of them within 7 miles of the Marble Arch, and I have no doubt that they may have been observed elsewhere. I cannot say whether they will or will not grow well out in open quarters at Kew, for I saw none there thus situated. Granting that none are planted out there, may I ask why they are not? Who would think of planting Retinosporas after seeing those to which I refer? It may be said that grand specimens are not looked for at Kew; but surely graceful natural development ought to be found there as well as elsewhere. Many go to Kew to see what they would like to buy for their own gardens, and it can never be hoped that

Retinosporas, grown as they are there, can ever be selected for that purpose; whereas, if planted out-of-doors, and in a thriving condition, their beauty would at once arrest attention. JOHN TAYLOR.

Hurdwicke Grange, Shrewsbury.

ON THINNING PLANTATIONS.

By ROBERT PHILIP.

THINNING is an operation in arboriculture subject to modification, according to the nature of the trees, or ultimate design of the plantation, to be operated upon. The same rules will not apply to Fir, hardwood, and mixed plantations; neither will they apply to an ornamental and profitable one alike. Few cultivators of trees in the present day will deny the necessity of thinning plantations composed entirely of hardwood or of hardwood and Firs; and fewer still will expect to rear a plantation composed of ornamental trees without due attention to timely and judicious thinning; but there are yet to be found parties in charge of plantations who believe (or affect to believe) that the best system of managing Fir woods is to allow them to thin themselves. The end and aim of all who thin trees ought to be to give those trees intended to fill the ground as the permanent crop the benefit of as much light and air around them as to keep them in a healthy and vigorous condition, light and a free circulation of air being indispensable for this purpose; and also not to permit more trees to occupy the soil than it is capable of maintaining. Trees, when crowded, are like cattle in a field where there are two for one which the pasture is capable of supporting in good condition; both may subsist in their half-starved state, but neither of them can be expected to come to anything like perfection. Some trees strike their roots downwards to a considerable depth in the soil, others keep them nearer the surface; but all draw what nourishment they derive from the earth, from the soil near the surface, or as deep in it only as the air can circulate; and, this being the case, they must have a reasonable space in which to extend their roots in quest of that nourishment. Where the soil is of that kind which prevents the roots from penetrating so deeply as their nature requires, it will not be capable of carrying so heavy a crop of timber; and to keep trees in a close state on such prevents them from rooting firmly, and also deprives them of their due nourishment. Trees, in such a condition, cannot be expected to remain healthy for any length of time, nor even to arrive at good dimensions. The too frequent practice has been, to leave twice the number of trees on such soil, from the very circumstance that they were not so robust and thriving as those on better soils; but we have no reason to expect that they should be so, although, were they thinned to a reasonable distance apart, it would very much improve them. By keeping trees rather thin than otherwise on such soil—which is always of poor quality—they arrive at larger dimensions, and live longer, although of rougher quality; thus affording both shelter and ornament. And, as in most extensive plantations there will be found spots of this kind of soil, it is of great advantage to have the whole extent filled with trees during the time the plantation is kept up. No universal rule can be laid down by any one for thinning, but general principles can be given sufficient for the guidance of those who want information. This will be evident, when we consider that few foresters are so far advanced in the sciences which demonstrate the quality of different soils so as to enable them to determine with certainty when and where trees ought to be thinned to a given distance apart. But every one can observe; and on careful and extensive observation we must rely until such time as we are better acquainted with the sciences referred to—geology, chemistry, and physiology, in particular. An accurate knowledge of these, and extensive observation, will qualify a forester to determine, with something approaching to certainty at least, what distance trees ought to stand apart in order to preserve them in perfect health, and to enable them to progress at the various steps in growth. Every district of country supplies lamentable evidence of thinning having been too long neglected, and, in many instances where it has been performed, it has been conducted on anything but rational, not to speak of scientific, principles. This state of matters is to be met with on the small property with a few acres of wood only, as well as on properties containing thousands of acres. In the first case there may be some excuse for the proprietor, as he has not extent enough to employ a properly qualified person, and must entrust the operations to a country carpenter, or more commonly to his overseer on the home farm, if he has one. These parties not knowing so much about the operation as the mere labourers under a forester of ordinary ability, it is no wonder that it should be ill performed. I have had frequent opportunities of examining plantations under such management. One, in particular, composed of Scotch Firs principally, with a very few Larch; these may have been about twenty-five years old, and in general healthy. It had been thinned by the land-steward, and the trees cut out and laid in lots for public auction. To my astonishment I found

that he had cut down the largest and straightest of the trees and left the smallest, bent, twisted ones, which had been rendered so by strong Whins and Broom having been allowed to rise with the young plants as the permanent crop. I found, on inquiry, that his reason for thus acting was because the bent trees would bring but a low price at the sale. Nothing can be more injurious to the future prosperity of a plantation than to thin for the purpose of making up a certain sum of money. Not a single tree ought to be cut, unless for the benefit of those left on the ground; as, if the plantation be properly managed, it is to the full crop, when matured, that the proprietor must look for the greatest profits of planting. There is, certainly, no reason why the thinnings should not be made the most of, keeping the general welfare of the plantation in view. Indeed, thinnings, under a good system of management, in many parts of the country, are a source of good profit; but the ultimate value of the crop, the maturity of the greatest quantity of clean, sound timber of good dimensions, ought to be steadily kept in view in every operation of thinning. I have said there is some excuse for the small proprietor, himself ignorant of the science, and entrusting the management of his plantations to persons more ignorant than himself. But I am perfectly satisfied that there is not only room for improvement on such properties, but that it can be carried out. Although foresters of ordinary ability are not agreed on forest management, still, with the knowledge which most of them possess who deserve the name, were there opinion taken on the spot by such gentlemen, they could give advice and instructions which would very much improve the state of things I have been describing. As to the proprietor of thousands of acres of woods and plantations, who has allowed them to be neglected and mismanaged, there can be no excuse, as the profit arising from such an extent of woods, well managed, would more than repay the employment of a forester of the best ability and skill in his profession. I have already stated that there is

No Universal Rule for Thinning.

A plantation composed entirely of Scotch Firs, planted on soil in every way suitable to their growth, requires to be kept thicker than any other kind of trees, in order to grow clean, useful timber; as the value of the Scotch Fir consists in this. From my own observation I am of opinion that the best rule which can be adopted in thinning Fir plantations is to keep the trees at such a distance from each other as to preserve the branches alive on one-half of the whole height of the tree, from the first thinning till the trees are forty years old, after which they ought to be allowed to assume their natural habit, which every one acquainted with the Scotch Fir knows to be a bare tall trunk, with a spreading top, small in proportion to the height of the tree when grown in its native forests. By the time they are from forty to forty-five years of age, if they have been well managed, they ought to stand so far apart as to require no more thinning. They will not, by the time they are the above age, be regular all over the ground, that is, they will not be any regular number of feet apart. Some may be a little too close for all arriving at maturity; but allowance must be made for a few dying during the remaining period they may occupy the ground, for were they thinned out to stand at something like 16 to 20 feet apart, then when one died a space twice as large would be made, and should two contiguous trees die a blank is made, and the wind makes havoc among the trees around. Scotch Firs, when so regulated during the time I have specified, will be found neither drawn up nor too tapering, but with girth of stem in proportion to their height. When they are so thinned that more than one-half of the whole height is covered with live branches, they are short in proportion to their girth near the ground; and, the branches getting too much space, grow large and produce coarse timber; but, when they are kept so close as to deprive them of living branches for much less than the above proportion, they get tall and drawn up, without sufficient strength of stem, and, when thinned, the wind waves them, and the one whips the other often to death, or renders them unhealthy for a time. I have had the charge of a plantation consisting chiefly of Scotch Firs, with a few Larches here and there through it, of about 600 acres, which was in a bad condition from being neglected too long. It was from fifteen to thirty-two years old, and large tracts of it had never been thinned up to the time it came under my charge. It has been very difficult to thin it, and it is not yet anything like what it ought to be for its age and height. My first object was to get all the dead and unhealthy trees, with a few of the overtopped ones, removed from those places which had never been thinned at all; then to go over the rest as fast as I could and give it a cautious thinning. I was not able for a number of years to get anything like regular periodical thinning performed, but directed my attention to the most necessitous parts. I have gone over it cautiously, generally every second year, and, except on the exposed sides and any rising ground, it promises yet to become a good plantation; but as it was so long neglected, and the

outsides had received rather a severe thinning, which unduly exposed the trees, one side in particular, where the soil is wet (although originally drained, the drains having been neglected), it will be impossible to recover. On the higher parts of the plantation, the trees having been kept so long in a close state, they have a very insufficient hold of the ground, and having slender stems for their height, with a very small proportion of top, they are liable to be blown down by every gale. On some of these parts it will also be impossible to keep sufficient trees for a full crop till they arrive at maturity. The only portion on which the trees have attained anything like the dimensions which their age and the nature of the soil would warrant us to expect is where lines of Larch and Scotch Fir had been planted alternately; the greater part of the Larches have been killed by disease, and the Scotch Firs, although too close in the lines, have had good space between them. Even here they are a very unequal crop. In addition to the regular thinnings, the whole extent of the plantation is gone over twice every year—in spring and autumn—and all the unhealthy trees cut down and disposed of. By this method there is a great saving; if they were left till dead the price would be from 2*l.* to 4*l.* per tree, while the labour of cutting and carrying out is nearly the same; whereas, before they die they bring from 6*d.* to 1*s.* 6*d.* each. A very great mistake has been committed in the management of Scotch Fir plantations, by keeping the trees too close on the outside of the plantation, from a fear of the wind breaking in upon it. On one of the sides of this plantation the trees are comparatively wide apart, and clad with healthy branches to near the ground; from this point the wind does very little damage, while on the other sides, where the trees are much closer, the damage is often great. When trees at the outside of a plantation are kept as wide apart as to allow their branches to be healthy from near the ground, they get a much firmer hold of the soil, and bring up strength of stem suited to their situation, and in this state they are healthier, and remain so for a longer period. I have been told that trees so managed will not defend the plantation against the storm, and that such a system of thinning the outsides will prove its ruin in course of time. But how comes it that trees standing singly in a park or hedge-row are seldom up-rooted by the storm? Nature adapts the growth of such trees to their circumstances; the free circulation of air through and round their tops causes them to throw out strong branches, and furnishes the tree with abundance of them. Clad with a large foliage, inhaling a quantity of the gases from the atmosphere, which give strength and stability to the plant, and the large space afforded for the ramification of the roots; these circumstances enable it to fix itself so firmly in the ground that no storm can uproot it. And, on the same principle will trees round the outsides of a plantation grow, and prove of more benefit as shelter to the interior than the unsightly bare poles too often to be met with in such situations. In order to have the outside trees of such a nature, it will be necessary, a year or two previous to thinning, to shorten the branches of those intended to be taken out, so as to allow those remaining to stand as close as possible, and not interfere with each other, or make too wide an opening. On the principle of keeping the trees close at the outsides, too many are left on the ground, and in such cases they are very insufficiently rooted, have little proportion of top, are more delicate in their constitution, and consequently more liable to die off, leaving blanks, which give the wind play amongst those left; from being top-heavy, of slender stem, and with roots confined within a narrow space, they get strained and loosened at the roots, which causes mere deaths, and so the evil goes on increasing until the plantation becomes entirely a ruin long before the trees have reached that maturity which the soil and situation would warrant us to expect. Where narrow strips are planted, it must be for

Shelter and Ornament.

If rightly managed, to attain these two objects, it will be impossible to combine this mode of planting with clean valuable timber, the same as in a large plantation. Good dimensions may be obtained if the soil be suitable to the trees planted, but it will be of coarser quality. My opinion is, where narrow slips are planted they ought to be managed on the same principle as the outside of a large plantation. Nothing is more common, yet nothing can be more erroneous, than strips left so thickly planted, for the sake of the shelter they afford, that by the time they are from thirty to forty years old the trees are a parcel of mere poles, with all shelter and ornament gone for ever, so far as they are concerned; whereas, were the trees kept wider apart, there is no reason why they should not live and preserve shelter and ornament till they reach the natural age of their species, if suited to the soil and situation. No doubt the mismanagement of narrow slips has led writers almost universally to condemn them; and, certainly, where shelter, ornament, and clean timber of good dimensions are the objects of the planter, they ought justly to be condemned; but the first two may be attained where there is

breadth enough for three trees only; less than this should never be planted in the form of a strip, a single hedgerow will answer the purpose much better. As strips are generally planted on exposed situations, care must be taken not to unduly expose the trees, by severe or sudden thinning, to the storm; this would render them unhealthy and difficult to raise above mere bushes. If it be a mixture of hardwood and Firs, and it is designed to keep these as the permanent crop, no better one can be chosen amongst the Firs than the Silver; it is evergreen, attains good dimensions, and, where it is allowed plenty of space, retains its branches from the base, and the thinning should be so arranged as to encourage it. As to

Mixed Plantations.

those composed of hardwood and Firs, or, let us say, those composed of a mixture of the Firs only, are not so easily managed as when each kind is grown separately in masses, Larch, Spruce, and Silver Fir, all being of the same habit of growth, can be grown intermixed with advantage, so far as thinning is concerned, as they all require more space in their earlier stages to develop themselves properly than the Scotch Fir; but it becomes a difficult matter to thin properly, to suit the growth of the Scotch Fir, and that of the others in the same plantation. Larch, Spruce, and Silver Fir will require to be so thinned as to allow them to retain their branches on three-fourths of their whole height during the entire period of their growth, whilst the Scotch Fir, as I have already stated, requires the branches preserved on one-half of its height to keep it in vigour and to make clean timber, and that proportion for one-half of the period of its growth only. I do not mean to assert that these proportions of top can be always exactly preserved, but the nearer they can be approached the better. I do not lay down rules to be implicitly followed under all circumstances, but merely give my own opinion, as formed from careful observation and experience in the district from which I now write. Some writers give the number of feet apart at which trees ought to stand at certain stages of their growth, and the number of thinnings they require. This I think a rule which will not be found applicable in all cases where it is recommended, as the soil, climate, and situation will necessitate a plantation of the same nature to be differently managed. I have found it necessary to thin a plantation this season which has been planted six years only. It is composed of a large mixture of hardwood, with Larch, Spruce, and Silver Fir for nurses. The Larches are 9 to 11 feet high, and 2 to 3 inches in diameter at the ground; the Silver Fir and Spruce from 3 to 4 feet high; the hardwood, 3 to 6 feet high. Besides taking out a number of the Larches, I found it necessary to shorten the branches of many of them which were interfering with plants not so far advanced. There is another plantation on this estate, consisting of Oak, Ash, Elm, Sycamore, with Larch, Spruce, and Silver Fir, as nurses, which will not be ready for thinning for three or four years, although planted at the same time as the last. The first was formed on ground which had been under agricultural crops, and the plants put into the ground after a crop of Turnips; the ground kept clean of weeds for three years. The soil is a damp rough clay. The second plantation mentioned was formed on ground which had previously produced a crop of matured Scotch Fir, and was planted three years after it was cut down; the plants here have done remarkably well, but are not so far advanced as those in the first-mentioned. The soil is poor—gravely-clay in some parts, and in others a few inches of moorish soil resting on a hard tilly sub-soil. The most of this plantation was drained 2 feet deep, and from 9 to 12 yards apart. Besides the last-named, there is a plantation of Fir, which I found it necessary to thin for the first time when about fourteen years old; another Fir plantation on the estate I have just thinned for the first time, which has been planted eighteen years, but I must confess it was in want of thinning three years before I could get at it. So much for the time to commence thinning, when planted from 3 to 4 feet apart. If it be intended to leave the hardwood trees as the permanent crop, using the Firs as nurses only, it will be necessary, previous to any thinning, to go carefully over the whole extent of the plantation and shorten any branches of the Firs which may be found interfering with, or over-topping the hardwood. This is a work which takes up but little time, and is of great service to the young plants, as it can be done when the hardwood is pruned, by merely going through with a hedgebill and shortening where necessary. Hardwood being more inclined to spread out in large branches, and less inclined naturally to rise with a central stem than the Fir tribe, requires great attention to thinning and pruning, so as to have the nurses cut away gradually; taking care that the trees bring up strength of stem proportionate to their height. Many a good plantation of hardwood is spoiled by neglecting to thin in time, the Firs having been allowed to stand so close that any hardwood trees which had not been choked and killed are seen rising to such a height with a weak stem, that, when the Firs are cut away, they cannot support themselves. And even although they should be as strong of stem as to support them-

selves, with the assistance of a little pruning, which such trees will always require to balance their tops, still they will be unduly exposed and liable to fall into bad health, and even die. Some of the hardwood, such as the Sycamore and the Ash, if once rendered unhealthy, are diligent again to restore to health; the Oak and the Elm are more easily recovered if they are not too far gone. Much shortening of the side branches of the nurses will be necessary in exposed situations before they are entirely cut away to preserve shelter to the plants intended as the permanent crop; but, where the situation is naturally sheltered, they will require less shortening, and can be sooner cut away. I consider that by the time the plantation is twenty years old in the exposed and fifteen years in sheltered situations, the nurses ought to be all removed. Where a mixed plantation of hardwood and Firs is wanted, Spruce, Silver Fir, and Larch ought to be kept; as, where hardwood will grow to ordinary dimensions, these trees will be found to answer best—the Spruce on the dampest parts, Larch where the soil is damp but not wet, and the Silver Fir on the driest parts of the soil. Scotch Firs should never be left among hardwood as a permanent crop, unless where the soil is of a very poor quality; for, although of a conical habit when young and in a close state, yet where it gets as much space as hardwood requires, it is very apt to grow rough and branchy, and the timber of little value. Nor is it so well adapted to preserve shelter as the others mentioned, which keep their branches alive on a larger proportion of their height, and are still valuable as timber. But in thinning a plantation of mixed trees, those which appear to thrive best on the soil ought in all cases to be encouraged, and left as the permanent crop; for, where there is a great variety of trees, all will not be found to thrive alike; and on no account should they be thinned and pruned the same year, such a course exposes them too much at once, and should be carefully guarded against at all times. Such thinning, instead of proving an advantage, will be found the very reverse; as the general temperature of the plantation is cooled too much at once, and the trees, instead of improving by the operation, will stand still for the first year at least; and, if the situation is exposed, for several years they will make little progress. As I have already stated, space enough to

Permit Light and a Free Circulation of Air

amongst the trees, and no more, is, without doubt, the condition under which they will thrive and grow most profitably; more than that will only induce the side branches to grow strong, which robs the main stem of its due nourishment, and produces coarse timber, or causes additional work to the pruner to keep these branches within due limits. Amongst trees of whatever species there will always be found some of coarser growth than the rest; these have a natural inclination to grow strong in their branches, and should be all cut out, if possible, in the course of thinning; for there can be no doubt the smaller the branches the cleaner the timber will be. I purposely abstain from giving the number of trees to be thinned out at any given stage or condition of a plantation. Some writers give rules for thinning so exactly, that the number of thinnings is stated, as also the number of trees to be thinned out at each operation, and the number left as the permanent crop. It is comparatively easy for any one—even a mere theorist, to sit at his desk and draw out rules for thinning; but when we would reduce these rules to practice they will often be found impracticable. Although general principles can be given, which may help to guide the inexperienced, mathematical rules cannot; not even by the most experienced practical men—far less by the mere theorist, who has had little or no experience. Theory and practice combined are what we wish to see more extensively brought to bear on all the operations in the cultivation of trees, but theory made subservient to practical experience, and practice divested of all old preconceived notions and prejudices—then, and not till then, may we reasonably expect to see improvement in arboriculture. No specified time for thinning a plantation can be positively stated, the general health and progress which it may have made since last thinned must, in a great measure, determine when it requires the assistance of the hand of man. Some years will prove more favourable to the growth of the Fir tribe, and others to the growth of hardwood trees, and should a few years succeed each other favourable to either, a plantation may want thinning as much in three years as it would in five not so favourable. Altitude and soil have also much to do in the progress of a plantation; where altitude is great and the soil poor, the trees cannot be expected to make the same progress as when they are on low ground and good soil. The thinning operations must be performed in a neat and careful manner by the workman, and the work conducted in as profitable and economical a way as possible. Where the trees are young, and not more than 6 or under 6 inches diameter at the root, it will be cheapest to cut them down with the axe, and the workman should be made to cut them over as nearly level with the surface as possible; if Heath or rank Grass grows round them, it should be pushed down with the

head of the axe in order to get them cut low. All trees above 6 inches should be cut with the saw, if they are suitable for sawing purposes. If the wood is cut and laid out in lots for public roup, it will always be found that the more the buyer's interest is studied the better a price will be got for the wood; for much depends on the way in which the trees are laid out to public view, as people at a sale have but little time to judge of the value of each lot, and have often but a mere glance at it. All trees of any size ought to be seen at once, and the different sizes all put in separate lots; nor should hardwood and Fir be put in the same lot; but, if possible, keep each kind separate. And another point to be attended to is to have at least one good cart-load in each lot, a large number of small worthless lots always have a prejudicial effect upon a sale; it takes up time to no purpose, and the purchasers get out of humour. The trees, when cut down, ought to be all carried; or, if too heavy for carrying on men's shoulders, dragged out to the nearest road leading out of the plantation. Dragging out trees is dangerous to those left standing, if great care be not taken, as it often damages the bark on the bare roots and lower part of the trunk. Where the wood is very heavy, and not on steep ground, it may also be carried out to the road by a junker; and this is not so injurious to the roots of the standing trees as dragging. All trees should be conveyed out of the wood whole, if possible, as cutting may spoil them for a particular purpose for which they may be wanted by some of the purchasers; and all branches dressed off the trees must be carried out and laid in lots, and sold along with the trees, if a sale for such can be got. Nothing looks more trashy than tops and branches lying about in the woods, and such rubbish encourages vermin and insects injurious to the growing trees. The decay of such rubbish by the gases arising from it also proves detrimental to the health of trees, especially if the plantation be composed of one kind only; but if it be a mixed plantation, the decay of refuse will prove beneficial, as such refuse of hardwood proves a natural manure to the Fir tribe, and *vice versa*. Objections may be raised on the score of expense in taking out all this rubbish, in coal and peat districts where fire-wood will not sell at any price; but although it should have to be burnt on the ground, I am prepared to assert that the better health of the plantation will repay all expenses; and where fuel is scarce, it not only refunds the outlay, but it will leave a good profit. Where the trees are of considerable size, either Fir or hardwood, great care is necessary in thinning to prevent the falling trees from injuring those left on the ground; where there is not plenty of space for them to fall, their tops should be lightened, and in some cases entirely cut off. This operation is performed by a man ascending the trees with a hand-saw, and commencing at the first branches, cutting the whole off till he arrives at the top; he then cuts off as much of it as is safe and convenient, by holding the saw in a slanting direction towards the root of the tree, and in an opposite direction from himself; this is the only dangerous part of the operation, and the man must keep a firm hold while the top falls, as the swing given to the tree may throw him off his balance. If the trees be much off the perpendicular, and leaning to any great extent to one side, in order to make them

Fall where they will do no Damage,

the man should almost always be furnished with a strong rope, and a large hook fixed to it, with a socket to fix it on the end of a pole; the pole may be from 20 to 35 feet long, according to the height of the tree to be cut, and fixing the hook on the end of it, it is pushed up through the branches, and hooked on to a strong one, and the tree made to fall in any direction wanted. By this pole much time is saved in climbing to fix the rope to the tree. When thinning on the home grounds, all trees should be cut as low as possible, for nothing looks worse than high stools, and, indeed, this ought to be attended to in all plantations, as they are not only unsightly, but become a great annoyance in carting or taking out the thinnings at all after times. The proprietor's forester, or a responsible person for him, should superintend all thinnings of plantations, and on no account allow the parties who purchase the wood to cut it for themselves; they are careless as to how they perform the work, provided they can do it cheaply for themselves, and many of the standing trees may be ruined by their carelessness. Much damage is often done to the growing trees by parties removing the wood from plantations, by knocking against them. The forester, or person superintending, should look well after this, and check it, as every piece of bark removed from any growing trees makes a blemish in the timber, and is injurious to its health. The expense of thinning will very much depend on the nature of the ground on which the plantation stands, and the price of labour in the district; the profits arising from the operation will depend on the way in which it is performed, and the price of thinnings in the market. But if the operation is judiciously performed, the health and progress of the plantation will amply repay all outlay on it; and the money-profit at the time ought to be

but a secondary consideration with those who wish to raise timber to good size, and retain a full crop on the ground. We trust the time is not far distant when thinning will be better attended to by proprietors of plantations, and the country no longer disgraced by a system of management which would induce the belief on the part of planters that no further care is necessary after planting but to receive the produce of their woods as a gift from Nature.—*Transactions of the Scottish Arboricultural Society.*

Daphne Fortunei.—This was sent to the Royal Horticultural Society by Mr. Fortune, from the Chusan Hills, Ningpo, and Shanghai. It is a small downy-branched bush, with thin deciduous opposite and alternate ovate-oblong leaves, covered with very soft fine hairs. The flowers, which generally appear very early in spring, are pale bluish-lilac, arranged in clusters of four, upon branches scarcely beginning to put forth their leaves. They are rather more than an inch long, covered externally with soft closely pressed hairs, and divided in the border into four roundish, oblong, obtuse, unovoid lobes, of which the two inner ones are the smallest. In the inside of the tube of the calyx are eight nearly sessile stamens in two rows, with narrow sharp-pointed anthers. The ovary is smooth, stalked, one-celled, with a small fleshy scale at its base, and a single suspended ovule; it produces abruptly from its summit a very short cylindrical style, ended by a capitate hairy stigma. No species yet described, approaches very nearly to this, which has been named after its enterprising discoverer; the seed being unknown, it can only be conjectured that it belongs to the Mezereum [division of the genus. It is a greenhouse or, perhaps, half-hardy shrub, and is a charming addition to this class of plants, more especially since it appears to be well adapted for forcing.

Seaside Trees and Shrubs.—*Abies Menziesii*, *A. nobilis*, and *A. orientalis*, *Acer creticum* and *A. monspessulanum*, *Arancaria imbricata*, *Arbutus* (most of the species), *Atriplex Halimius*, *Aucuba japonica*, *Baccharis halimifolia*, *Buddleia globosa*, *Bupleurum fruticosum*, *Buxus* (all the species), *Camellia japonica*, *Chamaerops humilis*, *Chenopodium fruticosum*, *Cineraria maritima*, *Colutea arborescens*, *Daphne Cneorum* and *D. pontica*, *Desfontainea spinosa*, *Elaeagnus* (most species), *Escallonia* (all the species), *Eranonymus* all the evergreen species), *Ficus carica*, *Garrya elliptica*, *Griselinia littoralis*, *Halimodendron argenteum*, *Hippobae rhamnoides*, *Hydrangea Hortensis*, *Ilex* (Holly) (all the species), *Lardizabala bitorata*, *Laurus nobilis*, *Lavandula Spica*, *Leptospermum lanigerum*, *Ligustrum* (the evergreen species), *Lycium europaeum*, *Myricaria germanica*, *Myrtus communis*, *Olea ilicifolia*, *Osmanthus ilicifolius*, *Pernettya* (all the species), *Phillyrea* (all the species), *Pinus macrocarpa*, *P. pinaster*, and *P. Sabiniiana*, *Pyrus salicifolia*, *Quercus Ilex* and *Q. Suber*, *Raphiolepis ovata*, *Rhamnus alaternus*, *Ruta graveolens*, *Santolina Chamaecyparissus*, *Shepherdia argentea*, *Tamarix gallica*, *Veronica Andersoni*, *V. decussata*, and *V. salicifolia*, *Yucca* (all the species), and *Zenobia speciosa pulverulenta*.—A. MONGREDIEN.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

The Chokeberry (*Pyrus arbutifolia*).—Can you tell me if this is the same as what is called the Chokeberry in Canada? Also, if the latter ever bears fruit in this country? I have two trees of it which I brought from Canada in 1863, and though they flower annually, they have never set their fruit. The fruits are small and many on a stalk, resembling a bunch of grapes, and the leaves, like the wild Cherry, turn red.—J. H. W. THOMAS, Belmont, Carlisle, Ireland.

Autumnal Tints of the Aspen (*Populus tremula*).—Your correspondent "E. P.," who writes from Braemar (p. 328) of the beauty of the foliage of this Aspen, must have finer examples of it there than have come under my notice. Here it is of a dark-green colour, without the slightest tint of crimson. Can you ascertain from "E. P." the nature of the soil on which it grows at Braemar, as we know that soil does occasionally alter the tints of leaves?—JAMES M'NAUL, Royal Botanic Gardens, Edinburgh.

The Venetian Sumach (*Rhus Cotinus*).—This is very handsome, in the form of a single specimen on Grass. In fact, those who have only seen it confined in shrubberies can form but little idea of the beauty of a well-grown plant of it in a good position. Its large bunches of downy pink inflorescence are produced in such abundance as to effectually conceal the foliage, and give the tree, at a short distance off, the appearance of a huge mass of delicately-tinted swan's-down. It also lasts in perfection for a long time, and the fact of its coming in as it does, after the majority of flowering shrubs are over, renders it all the more valuable, and well worth a place in the most unique collections of hardy shrubs.—JAMES GROOM, *Heath Hall, Suffolk.*

Remarkable Conifers at Beauport.—We are indebted to Mr. Fanneau de Lanne, of Sharstel Court, for the following:—I measured, he says, the Wellingtonia in Beauport Park, Sussex (Sir A. Lamb's), and found the stem to be 9 feet 10 inches in girth on the ground; at 3 feet, 6 feet 9 inches; at 5 feet, 6 feet. It measured about 99 feet round the branches on the ground, and I should say, although I could not measure it, that the height is between 50 and 60 feet. The size of an upright variety of *Cupressus macrocarpa* was as follows:—Circumference of stem on the ground, 9 feet 4 inches; at 3 feet, 7 feet 2 inches; and at 5 feet, 6 feet 6 inches. *C. macrocarpa*, with a flat top, had a circumference of stem, at 4 feet from the ground, of 6 feet; at 3 feet, 6 feet 8 inches; diameter of branches, 23 feet. There are numerous other fine examples of *C. macrocarpa*, and some grand *Arancarias* and *Pinus insignis*.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

The Kitchen Garden.

A HOT-BED may now be made up for forcing Asparagus. Where leaves can be readily obtained in quantity to mix with the stable-dung, the fermentation and preparation of the materials will involve less labour than would otherwise be the case; and there will be less danger from over-heating. In forcing Asparagus, a strong heat is not required; it would, in fact, be injurious. If a temperature higher than 60° is maintained, for any length of time, the heads will come up weakly and poor. What is required is a mild genial bottom-heat, such is usually furnished by stable-dung and leaves, employed in about equal proportions, well mixed and shaken together, and built up about 3 feet high at back, and 2 feet in front. I have often forced Asparagus where the heating power was furnished by means of hot-water pipes; but, on the whole, I much prefer the genial moist heat obtained from fermenting materials. When the bed is finished and the frame placed on it, a test stick should be pushed into its centre, to indicate when the roots may be safely planted, but if the bed has been properly constructed, it should be in a suitable condition in about a week or so after having been put up. The bed inside the frame should be levelled, and about 2 inches in depth of old tan or leaf-mould should be placed on it. The roots should then be carefully taken up and placed closely together all over the frame, finally covering with about 3 inches of fine light rich soil. Where white Asparagus is desired a greater depth of soil will be necessary; but the flavour of green Asparagus is superior to that of white. When Asparagus is forced in this way it does not require much water, as, with the exception of one watering with tepid water to settle the soil when the roots are first introduced, the moisture arising from the decomposition manure will be sufficient to keep the bed in a healthy condition. Cover with mats on cold nights; or, when necessary to keep up a regular temperature, and give air freely when the young heads push through the soil, to flavour and strengthen them. The above, I believe, is the best plan for forcing early Asparagus, but it involves the destruction of the roots, and, therefore, a constant succession of fresh plants should be annually brought forward to keep up the stock. A new bed should be filled about every three weeks if a large and constant supply is required. After Christmas, when the days lengthen, some arrangement might be made by which some of the permanent beds might be forced; the produce from these would be finer and better than that from frames, and no serious injury need be done to the beds, i.e., if they have not been too much exhausted by too much cutting. Take advantage of fine dry days to take up such crops as Carrots, Salsafy, Scorzonera, and Beet. Parsnips keep best in the ground, and a part of the Salsafy and Scorzonera will also be better left in the ground till after Christmas than lifted now. Beet should be handled with special care, for, if cut, bruised, or otherwise injured, the roots will not keep, and the colour and flavour will be spoiled. A considerable portion of the crop of roots will keep best if clumped in the open air (but not in large heaps), covered with straw, and by-and-by a thin covering of soil should be added and beaten smooth with the spade to throw off wet. A sufficient quantity for present use might be placed in a dry cool cellar or shed. Pot a few roots of Chicory and place them in the Mushroom-house; it will be a valuable help to winter salads if a succession is kept up. Endive will now require considerable attention to have it in good condition; tie up a few plants every dry day, and cover them with pans or something to throw off rain; for, if exposed to damp, they soon decay. Have a sufficient stock of it in some position where it can be easily sheltered from frost. French breakfast and black Spanish Radishes may yet be sown on a warm south border; the former kind turns in very quickly.—E. HORDAY, Ramsey Abbey, Hunts.

Hardy Fruit.

As soon as the leaves of early Cherries and Plums begin to fall, proceed with the pruning and nailing of wall trees. This is alike humane and economical, for a man will do ten times more work on a wall-side, in early autumn, than in mid-winter, and also do it better. Fruit trees, too, do not suffer from early pruning and training; but, on the contrary, bear close pruning well; and Plums especially bear and look best treated somewhat on the principle of Morello Cherries—that is, pruned and trained so as to bear largely on the young wood. By such means the trees are kept closer to the wall, and partially renew their growth every year. Cherries may also be treated in the same manner, though all the large fruiting varieties bear close spurring for many years better than Plums. Old trees, too, very often bear their spurs close cut, not only without injury but with positive benefit to their continuous fertility. By

studying the characteristics of spurs, the skilful pruner will generally find some buds near their base that may be cut back to with impunity. Of course, no one would think of removing all the more prominent spurs at once, unless he could afford to lose a crop; but, by cutting a few of the largest out annually, they may be kept within a reasonable distance of the wall, and the form and beauty of the tree, as well as its constant fertility be preserved. Again, in the laying in of young wood, we find the means of dispensing with the old in due season, as the great art of successful pruning is to prune for a crop, so as to renew the growth, and so add to the strength and vigour of the tree. There is yet one more advantage in early pruning. The wounds made now heal faster and sounder than those made later or inflicted in the spring. These are points of immense importance to the future well-being of the tree. Bad heals, if I may so call them, constitute the most fruitful sources of disease and death. No larger wounds than are absolutely necessary, should be, in fact, the motto of all skilful pruners, who should also cut in such manner and at such a time, as to ensure speedy healing over. Smoothness and a short angle from the lower to the upper side of the cut, so that no moisture can rest on the wound, is one of the surest methods of helping it to heal over rapidly. A cut with a ragged edge, jagged surface, and wounded bark, will hardly heal at all. Cuts made in frosty weather are more like breaks than new smooth wounds. Whatever appearance the surface may present, the tissues are bruised and wrenched asunder; and this, as well as the effect of the cold on a raw wound, is the cause of most of the evils arising from pruning during hard frost. By pruning hardy trees now, the wounds become healed over before the cold weather sets in.—D. T. Fish.

Indoor Fruit Department.

Pot Vines placed in heat about the first of the month will be showing as yet but little signs of growth; do not, however, increase the temperature in order to force them on more rapidly, for the slower they start at first the stronger will be their growth. If a slight acceleration is required, it should be after the bunches are formed and the berries are set. Be careful not to over-water; at present the soil should be kept rather dry than wet, there being as yet little root action. When water is given it should never be colder than the bottom-heat in which the plants are plunged, or the soil in the pots. If this be 75 the water should be 80. Chills in all forms must be avoided; young Vines which were propagated from eyes in the spring, and grown on in pots throughout the summer for planting next spring, should now have ripened their wood. Those fully matured should be wintered in a cool airy house. An open shed, covered at top, answers very well for this purpose. The canes of the Muscat take longer to ripen; these, and any other sort not yet brown to the extreme points, should be retained in heat until they acquire that condition. It is a mistake to move Vines from a warm house to a cold situation before they are thoroughly ripe. In such a case they are starved into rest in a way that is never productive of good results. Here we have annually many thousands of young Vines both for fruiting in pots and for planting out. They are struck from eyes early in the season, and as soon as roots enough have been formed to provide sufficient support they are set on a hard concrete floor and grown on rapidly, till, by the month of July, they are fully developed; ripening then begins, and already they have shed their foliage, have prominent eyes, and are hard and brown to the very points. This is a trying period for Grapes still hanging on the Vines. Heavy rains and muggy atmospheres are not easily contended with, especially when there is much foliage to keep up a circulation of sap. It is under such circumstances that the advantages of protecting the borders are fully shown. If the wood of these is not yet ripe lose no time in effecting this desirable end; husband sun-heat for the purpose rather than keep up strong fires, the effect of the latter being to shrivel the fruit. Cuttings of *Geraniums*, propagated in autumn, and similar plants, have often, through necessity, to be wintered in Vineries, but their presence in houses containing ripe Grapes, is often most disastrous. Vineries in which the fruit has been cut should alone be used for such a purpose. Pines of the Queen variety intended for early starting and fruiting, should now, as a rule, be perfectly at rest; see that the temperature does not exceed 59; for, if not allowed to exceed that, they will start into fruit with greater certainty when a higher temperature is applied to them. Between 300 and 400 Queens now being treated as an early batch here, have received no water at the root for three weeks, and if they do not absolutely require it, they will not get any for another three or four weeks more. See that the soil in which newly-rooted suckers are grown, does not get into bad condition. The bottom-heat for such stock may now be reduced 10°, too much growth being undesirable at present; slow substantial firm growth is what is needed to brave the winter season successfully. Bear in mind that

too much water at any time is as injurious as too little.—J. MUIR, *Clonelfords*.

Orchard House.

It is now time to refresh orchard-house trees in pots; the summer soil in which the trees have been feeding will be quite exhausted, and should be taken out of the pot about half-way down; more or less, it will probably be full of fibres. Care must be taken to preserve the main roots as much as possible, but the rootlets with which the soil is crowded may be removed; they have done their duty and are now useless; when the pot is cleared, fill in with the new soil, ram it well down with a wooden pestle, give a good soaking of water, and the tree will be ready to do its duty again next year. The soil should have been prepared at least six months since (a year is better), and should consist of good turfy loam mixed with about one-third of its bulk of rotten dung, and ought to have been turned over three times since it was deposited; if the natural soil is deficient in lime it should be added in the shape of old lime rubbish or, failing that, chalk. Place the trees in their winter quarters for facility of protection in very severe weather, and during dry sunny weather give water about three times a week. The open space which will be

made in the orchard-house may be filled up with evergreens in pots. The best implement to pick out the soil in the pots is an iron rod about an inch-and-a-half in circumference and 9 inches long, the handle being 5 inches; for scraping out the soil use a small pair of claws, made as in the accompanying little illustration.—R.

Indoor Plant Department.

In conservatories, the earliest *Cyclamens*, autumn-flowering *Heaths*, forced *Camellias*, tree *Carnations*, *Oleanders*, *Begonia Weltoniensis*, *Cassia havigata*, *Cypripedium* insigne, and a few other cool-house *Orchids*, young *Chorozemas*, *Tremandras*, *Hedera fuchsoides*, *Lasiandra macrantha*, and a few other plants, keep our conservatories at present gay with flowers. *Fuchsias*, a few *Acacias*, *Plumbago capensis*, and some *Roses* planted out in borders still continue to bloom admirably. Some of the taller-growing *Chrysanthemums* should now be taken indoors and placed amongst the *Camellias*, *Rhododendrons*, &c., in the beds. The dwarfier ones should be set on the side stages; but, where there is convenience, such plants should be kept in separate houses until they begin to bloom. If the tops of some of the shoots with flower-buds on them are taken off, and rooted, they will form nice bushy small plants, which will come into bloom before Christmas. Plants of tree *Mignonette* should be trained up to neat stakes, at the top of which should be fixed trellises for them to be trained over. Some *Carnations* should be potted so as to come into bloom a little later in the season than the others. Berry-bearing *Solanums* form attractive features in cool-houses. Some of their fruits are beautifully coloured, whilst on other plants they are still in a very young state. *Skimmia japonica*, now laden with fruit, planted along the front borders of conservatories in the natural style, is exceedingly attractive. Plants of *Everlastings* should be kept in airy houses; they should never be put outside during summer, nor forced in bloom. Show *Pelargoniums* will be breaking freely. Those required for early blooming should be re-potted, some into larger pots, and others into the same sized ones. Those, however, that are only intended for late blooming should still remain in the old pots. But the plants should be elevated, so as to be near the glass. Young plants in stoves still in active growth should be well watered and kept in the warmer corners. Washing leaves and cleaning plants from insects ought still to be the chief operation in this department. *Euphorbia jacquiniiflora* and *Poinsettia pulcherrima* should be kept as near the glass as possible. Young plants of these should be plunged in bottom-heat near the glass, so as to induce good crowns. *Gesneras* are now becoming attractive; those that have come fully into bloom should be kept a little dry, but those that have not opened their blooms should be supplied with a little weak manure-water. *Caladiums* should now be gradually dried off. *Achimenes* and *Gloxinias* that have done blooming may be stored under stages and on side shelves to dry. Let *Dipladenias*, *Clorodendrons*, *Stephanotis*, and *Allamandas* be loosened from the trellises on which they have been trained, and attached loosely to cords placed near the glass. In this way they ripen their wood better than in any other. They enjoy a tolerably warm temperature and a moderate, though decreasing, supply of water. *Ixoras*, which still continue to bloom, may be shifted into larger pots or shaken out of those they occupy; in the latter case their roots should be reduced, and they should be again re-potted into similarly-sized pots. Newly-potted plants must be encouraged in growth by being plunged in a brisk bottom-heat. Climbers that are obscuring the light from plants underneath them should be thinned out, and thoroughly cleared from dust and insects.

Flower Garden and Pleasure Grounds.

Between cold and damp, and the injurious effects of the slight frosts which have already been experienced, the beauty of our flower gardens may now be said to have, in a great measure, departed; and watching the gradual, but sure decay of the cherished plots of flowers, however seasonable and suggestive it may be, cannot be considered as the most pleasing of contemplations; where, however, a system of spring bedding is intended, no interregnum should be permitted, and the flower beds must be planted again as soon as possible. It may be taken for granted that all summer bedding plants intended to be preserved are, by this time, potted up and placed in their winter quarters; while the remainder should be cleared away, and the soil of the beds, after the necessary preparation, should receive at once a stock of spring-flowering hardy herbaceous plants of various sorts, early flowering bulbs, &c., such as have already been enumerated in previous calendars, together with dwarf berry-bearing and ornamental foliaged shrubs of various kinds, such as variegated Yews and Hollies, Aucubas, Retinosporas, Euonymus of sorts, Skimmia japonica, green and variegated Ivies, &c. Spring bedding necessarily differs materially from that of the summer season, and a simultaneous and gorgeous floral display is not to be expected, nor is it to be desired. The quiet beauty of early spring flowers is more calculated to call forth love and affection than to excite admiration and surprise; it is, therefore, seldom advisable to adhere so closely to the grouping system as is generally done in carrying out a system of summer bedding. Possibly the most satisfactory method to pursue, in furnishing flower-beds and borders at the present season, is to use for the purpose a judicious combination of spring-flowering bulbs, early flowering hardy herbaceous plants, and annuals, with dwarf ornamental shrubs of various kinds, by the aid of which an immediate effect is produced, and which will be increased, as the season advances, by the gradual development of the early flowering plants and bulbs. As soon as the planting of all beds and borders has been completed, let everything connected with the flower garden be again put into proper order. Lawns and Grass belts, should all be mown, for possibly the last time this season; leaves should be swept up, and gravel walks cleaned and rolled; and, when all this has been accomplished, attention should at once be turned to any alterations which may be contemplated, and which may necessarily involve the removal and transplantation of trees and shrubs, the planting of Box or other edgings, and the re-laying of turf, &c. The present time is unquestionably the best during the year for accomplishing such work, as there is yet ample time to allow turf to become established, and trees and shrubs, which have been moved, to put forth fresh roots, and to some extent establish themselves in their new situations before the ice king is likely to paralyse for a time, all such efforts. Whenever the weather is mild, give abundance of air to rooted cuttings of bedding plants, which should also be frequently examined and all dead and decaying leaves, &c., at once removed; giving water sparingly, and never until the soil is somewhat dry. If not already done, cuttings of bedding Calceolarias may now be inserted, placing the pots or pans containing them in cold pits or frames, and keeping them in a close atmosphere for a time; and as free from drip as possible. When fairly rooted give air during mild weather, and water when required, and the protection of mats, or other covering, during severe frost. —P. GRIEVE, *Culford, Bury St. Edmunds.*

Roses.

The season for selecting positions for new Rose-beds, and for laying out new Rosaries has arrived. In the first place, such situations should be well drained; remove the surface soil and take out the sub-soil (*i.e.*, if it is stiff clay or gravel) to a depth of about 2 feet; procure some good loam or fresh turfy soil and mix it with the surface mould, working into it plenty of good stable-manure, and with this compost fill the beds, leaving them slightly rounded in order that rain-water in winter may not stand on the surface. In the case of sandy or gravelly soils, where the surface is very light, it is advisable to mix with it a little clay, for I find that the Briar stock does best in a heavy soil. In districts in which there is a good depth of loam, all that is necessary is to trench it 2 feet deep, and to work into it plenty of manure. In this, Roses will succeed satisfactorily. Whatever may be the character of the ground it is best to have it ready for the plants a fortnight or three weeks before planting. As regards pot Roses, take all required for early and late forcing into cold pits, or plunge them in some sheltered spot out-of-doors, where, if possible, rain and frost will have little effect on them, for, if allowed to get saturated with water, and frost sets in, it will kill most of the tender varieties. Where autumn-blooming Roses can be afforded a slight covering on frosty nights they will continue to bloom much longer than they otherwise would do. Cuttings may now be put in of some of the

free-growing varieties, either out-of-doors or in pots set in cold pits. —F. G.

Trees and Shrubs.

Besides evergreens, mostly all the Pine tribe are fit for planting out this month, and planting of two-year seedling or bedded Scotch Firs into nursery rows may be done advantageously. Prepare ground for young plantations, draining, fencing, and making pits for the plants. Gather tree seeds; the following, amongst others, should be ripe this month, and are best sown as soon as possible after being gathered—*viz.*, Horse and Spanish Chestnuts, Walnuts, and Oaks. Kinds that would suffer from spring frosts, such as Beech, Maples, &c., should be kept till sowing time in February or March. Thorn, Beech, and Privet hedges may now be planted advantageously. —D. S.

Bouquet Flowers in Season.

Our flower markets now contain a good supply of cut flowers for all purposes of decoration, from the tiny button-hole bouquet to the large centre piece for the adornment of the dinner-table; amongst other varieties obtainable may be enumerated the following:—Whites—Bouvardias, Camellias, Carnations, Forget-me-not, Gardenias, Heaths, Pelargoniums, Roses, Stephanotis, and Tuberoses; scarlets—Bouvardias, Camellias, Carnations, Heaths, Pelargoniums, crimson Roses, and Gladiolus; blues—Cornflower, Forget-me-not, and Agapanthus; purples—Heliotrope and Violets; miscellaneous—Echscholtzia, Mignonette, Sweet Sultan, Fuchsias, variously coloured Roses, Pelargoniums of different hues, Statice latifolia, Petunias, Arbutus flowers, Veronicas, and many others. Button-hole bouquets consist for the most part of a yellow Rose bud, or something in that way, supported by a few pips of scarlet Bouvardia and blue Forget-me-not, the whole being backed by a frond or two of Maiden-hair Fern. Coat flowers consist of a mounted Camellia, or Gardenia bloom, resting on a little green foliage. Hand bouquets are composed of so many varieties of flowers that it would be of little use to enumerate them. The little wax-like bell flowers of the common Arbutus, though but seldom used, are nevertheless most useful in floral arrangement of many kinds; before they are employed, however, they must be divested of all leaves, which are heavy, and quite out of keeping with the delicate little blooms. Thus set free, and mounted on wire, they are quite equal to Heath in a coat bouquet. At present, there may be bought in Covent Garden Market quantities of a very small-sized white Michaelmas Daisy, which, where other flowers are scarce, will be found to be useful. Being light and airy-looking, it does not tend to give any arrangement in which it may be used a heavy appearance. A pretty and, at the same time, inexpensive arrangement might be made as follows:—Take a triplet Hyacinth glass (but, if that is unobtainable, some other kind will do, provided its form is somewhat in harmony with that of the other), the Daisy referred to above being white, almost any colour will harmonise with it, but scarlet and blue will make, perhaps, the most showy associates for it; then, as a scarlet, nothing can be more effective than the common Zonal Pelargonium, and as a blue there are still some Cornflowers to be had or Forget-me-nots. Pink Pelargoniums might be used in place of the scarlet; and, if the pink be selected, a few bunches of a pink and white Fuchsia added would enhance the general effect. These materials, neatly arranged, would look well and cost but little. —A. HASSARD, *Upper Norwood.*

Cettagers' Gardens.

As ground becomes vacant, some plan of cropping for the ensuing year should be formed, in order that manuring and cultivating, according to the crop intended to be grown, may be systematically carried out; for fresh manure, that would promote a luxuriant growth in a green crop, such as Cabbage, would probably spoil the quality of a root crop, such as Potatoes or Carrots. These succeed best in soils moderately rich in manure, but deeply worked, so as to withstand the effects of drought. Trenching should not in all cases be performed in the same manner, as when the sub-soil is bad in quality, only a small portion of it should be brought to the surface at any one time; the bottom spit, however, should be thoroughly broken up and all kinds of garden refuse mixed with it, by which means, all kinds of soils may in time be improved both in quality and depth. This is a good season for carrying out alterations, such as making new walks, or repairing those already made, as trees of any kind that happen to be in the way, may now be safely lifted. Any unproductive or worthless varieties of fruit trees should be rooted up at once, and a few healthy young ones planted in their places, taking care that the ground is properly prepared for them. Do not dot them about as if self-sown, but plant them so that the shade from them may not interfere with the regular open spaces devoted to vegetables. The outdoor display of flowers will, of necessity, become weekly more limited, but increased neatness should be made to, in some measure, compensate in this respect for any lack of beauty. —J. G.

NOTES AND QUESTIONS.

[The following notes and questions came to hand or were answered too late for insertion in their several departments.]

Sea Buckthorn (*Hippophae rhamnoides*).—We have received from Mr Wm. Paul a branch of this useful hardy shrub literally a rope of little round orange-yellow berries, that must render a bush of it highly ornamental. It grows naturally on sandy soil, and on comparatively bare cliffs on some parts of our eastern coast.

Acacia lephantha, as a Table Plant.—Permit me to direct "W. T. P.'s" attention to the usefulness of small plants of this *Acacia* for table decoration. I have had a pair of small plants in daily use for some time past, and when on the dinner table they looked quite like some light growing Fern. The effect of this plant for table decoration is worth a trial; it is inexpensive to purchase, and the atmosphere of heated rooms does not seem to affect it as it does more tender plants.—A. B. N.

Fields of Sweet Briar.—All along the coast from Prestonpans to Aberlady in East Lothian, there is a perceptible odour of Sweet Briar, which may be found growing there by the acre, loading the air with its delightful perfume. Even the rabbits, which are very numerous there, seem to enjoy its cover, holding, as they do, in and out from under its fragrant protection. They, no doubt, eat the young shoots; hence its dwarf and scrubby appearance, and inclination to creep along the ground and multiply to an unlimited extent.—H. K.

Trees to Stand the Sea-breeze.—I have had a turn through Connemara lately, and on Saturday week ascended "Maclaren," at the mouth of the Killary, which is nearly 3,000 feet above the sea level. I, however, found nothing on it save the very commonest plants. I had an opportunity of seeing some of the plants which grow best exposed to the sea-breeze of the Atlantic. *Pinnus insignis* is a most valuable plant, and by far the hardiest of the genus there, standing where the Scotch Fir cannot lift its head. *Thuja plicata* borealis is also very hardy, and suitable for planting there. The finest evergreen is *Eucalyptus macrantha*, which grows as large as a Laurel bush. *Fuchsias* are the best hedge plants.—D. MOORE, *Glenties*.

The Fruiting Duckweed (*Nertera depressa*).—I was much pleased to see some plants of this little gem, the other day, in the nurseries of Messrs. Dickson & Co., Edinburgh. It is a small prostrate Alpine plant, exceedingly pretty and useful, either on rockwork or in pots. A light sandy soil suits it admirably. The flowers, which are white, are small, and the fruit, which is transparent and glistening red, resembles miniature Holly berries, which seem strewn amongst the foliage. The appearance of the small berries, nestling amongst the leaves, which are small, oval, and dark green, is strikingly interesting; altogether this is one of the most charming little plants with which I am acquainted.—J. MITT, *Clonsilla*.

Ivy on Cemented Walls.—I am about to build a house, and I would like the outside walls covered with Ivy. What I am anxious to know is, will Ivy grow on the walls if they are covered with cement smoothed and marked into squares to imitate stone, or whether it would be better to cover them with cement rough cast? In laying out the ground, I am following the instructions given in the "Wild Garden," and I have thought that if I could get the house covered with Ivy, it would be in keeping with its surroundings; and that it would also help to encourage birds, of which I am very fond.—R. A., *Worthington, Cumberland*. Ivy will succeed very well against cemented walls after it has been planted about six months. Take care to well break up the ground in which it is to be planted, and if the existing soil is bad, remove it and replace it with good earth.]

Lencopogon Cunninghamii.—This is a winter-flowering plant not sufficiently known in gardens. It is a white-flowered plant of great elegance, bearing tiny tufts of flowers and leaves, each tuft being a miniature bouquet in itself. For what are called button-holes, it is unsurpassed even by white Heath for long endurance. We have been so accustomed to quickly get up flowers, that elegant hard-wooded lasting plants have been overlooked. Any nurseryman, I imagine, who got up a houseful of this elegant plant would meet with a ready sale for it. Being such a quiet-looking plant, many might pass it by without notice; but when pointed out, it never fails to command what it deserves—admiration. It is a greenhouse plant, and thrives best in sandy peat, under the treatment usually given to Cape Heaths. I never saw it planted out of pots in a conservatory; but I imagine that it would make good growth treated in that way, and its tiny panicles of flowers would be enlarged under such circumstances.—H. K. F.

New Pink-coloured Perpetual Carnation.—Comparatively few lovers of plants know that there exists in commerce a pink-flowered Carnation of the large-flowered *Souvenir de la Malmaison* section. It was sent out by Messrs. Methven & Co., Edinburgh; although a somewhat coarse flower, the old flesh-coloured variety is still a great favourite, flowering, as it does, where there is a series of plants, all the year over. The pink one mentioned is quite as good and useful, and, no doubt, in time, will become quite as popular as it deserves to be. Its habit is identical, judging from young plants, with that of its fellow. It is in every way a commendable plant, and worthy of further distribution among lovers of what are commonly called tree Carnations. Whether the pink will equal the flesh-coloured one in size of flower, which sometimes under good cultivation measures 6 inches in diameter, remains to be seen.—H. K.

Shanked Grapes.—I send you some diseased Grapes, which I should be glad if you or any of your correspondents would tell me how to combat.—S. H. T. [The Grapes are badly shanked. The shanking of Grapes is produced through various causes, which it is difficult to describe. It is generally owing to weak or deficient root-action. The cause may have been dryness at one time, and then excessive wet, resulting in sourness of the soil, which has caused the roots to perish. Stripping off a great quantity of leaves at one time is also supposed to have the same result. We have frequently noticed shanking when the Vines grew in borders rich with humus, resulting from many yearly deposits of manure on the border. Excessive cropping is also a sure promoter of shanking. If your borders are imperfectly drained, as we presume they are, remove all the soil, except that immediately about the base of the stem, down to 4½ feet below the surrounding level, then bottom with concrete 2 inches thick; on this place a 6-inch layer of roughly-broken stones, which should be covered in with large turves, and a drain should be made along the front sufficiently deep to carry off superfluous water; the remainder of the border should then consist of roughly-chopped turf, to which has previously been added a liberal quantity of ground bones; crop the Vines lightly for a season, and there will be little danger of shanking.]

A Grumble about Dinner-table Decoration.—A writer in the *Pall Mall Gazette*, is despondent over the consequences of modern fashion in the dining-room. "I know no greater feeling of dejection that ever comes upon me than when from my place in the column that moves into the dining-room I first catch sight of the table. I know I shall have to sit there for two or three hours, with no greater variety of talk than I can get by turning from the lady on one side of me, whom I have brought in, to the lady on the other side, who has been brought in by some equally unhappy gentleman. There was an Egyptian herald of mighty voice, whom Herodotus tells us of as one of the host with which Darius invaded Scythia. When this monarch, in his retreat, arrived at night at the Danube, and found his bridge of boats gone, he sent for this man, who standing by the bank could make his voice heard at the other side of the stream. Now, Sir, if I were as highly gifted as this herald, I should not despair of making myself heard even across a modern dinner-table; but my lungs are of but moderate capacity, and when I shout to Histieus the Milesian, Histieus cannot hear me. Much as I miss the narrow table of my younger days, no less do I miss the dark colour of the mahogany. Long before dinner is over my eyes suffer from the glare. Above me and all around me there is an excess of light; beneath my eyes is the dazzling table-cloth. I would wear, if I had but courage, the pair of coloured spectacles which I brought from Switzerland, and which afforded me such pleasant relief under far less trying circumstances. How pleasant it used to be in old days to see the white table-cloth rolled up and carried away. How I should now delight, if only I dare, to give it a pull at one end and to carry it and the contents of the greenhouse that it bears right off the table. The fact is, that we have allowed the ladies to turn that which should be the pleasantest of all meetings into an occasion of the vilest of all displays. A ritualism, differing in reality but little from that which has crept into churches, has invaded our dinner-tables. If we had not our clubs to which to fly, our case would be a desperate one indeed. Now, Sir, when I dine, I like to dine at my ease. I like to dine in a cool room, in a quiet light, and in a small company. The ladies, I fear, take too much pride in these solemn festivities ever to consent to give them up. They will, in spite of our protestations, go on making broad their tables and enlarging the borders of their table-cloths. They might, however, keep their wide tables, their greenhouse plants, their blaze of gas, their heated air, their crowded parties, for all the fools of their acquaintance. The young Ritualist carter would always be there to say grace, and to lend the sanction of the Church to the ostentatious display. Sensible people should be asked a few at a time to enjoy at a narrow table good food, good wine, good air, and good talk."

Almeria Grapes.—During the last few years the growth of this Spanish Grape has very extensively increased. Shipments are also earlier than formerly, as of late they have commenced to arrive in London about the middle of September, when there is little or no demand for them, in consequence of the heavy supplies of Lisbon. The latter, on account of their non-keeping quality, are always sold immediately on arrival, and generally at prices far below the usual run of Almeria.

THE GARDEN HARVEST.

Oh, favours old, yet ever new;
Oh blessings with the sunshine sent;
The bounty over-runs our due,
The fullness shames our discontent.

We shut our eyes, the flowers bloom on;
We murmur, but the Corn ears fill;
We choose the shadow, but the sun
That casts it shines behind us still.

Give us with our rugged soil
The power to make it Eden fair,
And richer fruits to crown our toil,
Than summer-wedded islands bear.

Who murmurs at his lot to-day?
Who scorns his native fruit and bloom,
Or sighs for dainties far away
Besides the bounteous board of home?

Thank Heaven, instead, that Freedom's arm
Can change a rocky soil to gold;
That brave and generous lives can warm
A clime with northern ices cold.

And by these altars wreathed with flowers,
And fields with fruits awake again
Thanksgiving for the golden hours,
The early and the later rain.

—JOHN G. WHITTIER.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare*.

THE EARLY OPENING OF KEW GARDENS.

The popularity of the Royal Gardens at Kew is a long and well-established fact, to which each annual report bears full and ample testimony by its record of the thousands and hundreds of thousands who visit those gardens yearly. The motives which induce these visitors to go to our national botanic garden are, as a matter of course, exceedingly diverse. That is a fact no observant visitor who has mingled with the crowds on a summer's afternoon, and listened to their conversation, will gainsay. Some, it will be found, are bent on study—purely botanical; these are few and far between, and possibly may be more frequently found turning over dried specimens in the herbarium, and analysing equally dry botanical descriptions, than investigating plant structure at the fountain head in a living state. Others, by their lively and somewhat boisterous mirth, indicate at a glance that they are gregarious; and, of a truth, they come in what may well be denominated shoals, prepared to derive a part of their enjoyments from the many interesting objects the gardens present; but an equally great proportion from the badinage that passes freely amongst themselves. These constitute the great mass of visitors. Then, again, we have the vigorous constitutionalist, who goes to acquire a well-sharpened appetite for the good things which constitute a dinner at the far-famed "Star and Garter." But these are not all. Frequently you may see representatives of another, and an essentially distinct, class—men who usually affect the solitary—at least, whose companionship consists in a note-book, and whose horny hands indicate at once that, albeit literary they may be on that occasion, they are wont to wield a heavier implement than either the pen or the pencil; this last belongs, at a glance, to the horticultural class. The very interest they evince in making notes at once confirms us in the fact that they love their business, profession, or calling, whichever term you like to accept—"profession," I think it is entitled to, seeing that it dates back through all time, and claims priority to all others; be this as it may, you will generally find that such men are early at the gates. Many come a long distance, and as their visits to Kew are necessarily few and far between, they are anxious to utilise every spare moment. Of this class of visitors some are young, ambitious to acquire during their London visit or sojourn, as the case may be, all the information on plant lore they possibly can; others are old weather-beaten representatives of the craft, possibly kings and princes of horticulture in their own respective localities, and consequently anxious to maintain their well-earned reputation by gleanings such information as abounds in the royal establishment. It is on behalf of this class of visitors, who, though comparatively few in number, possess a sort of representative character that increases their importance in a manifold degree, that I purpose making a few remarks on a topic which is not only uppermost in the gardening periodicals, but is deemed worthy of ventilation in the columns of the daily papers. By the way, I fear that the ventilation is what must be called a down draught, as your correspondent (see p. 357) appears to reckon the boon which the earlier opening of the gardens would confer on the public, as not to be gained without such a sacrifice in the efficient management of the institution, such as no public advantage would justify. The suggestion that the number of attendants would require to be doubled were the gardens opened to the public, say at ten o'clock, is so patent an absurdity to any practical mind, that I am disposed to pass it over without comment—beyond this, that it appears to lead to the inference that during the time the public are admitted to the gardens, one half of the staff would be doing nothing, and the other assisting them in that arduous operation. The actual work of the establishment to be done by the two combined, prior to the

opening of the garden to the public; now, knowing as I do, the authorities at Kew, great and small, I cannot for one moment imagine that they would endorse such a necessity. Let us, supposing the early opening movement were carried out, analyse the probabilities consequent thereon. Supposing the gardens were opened at ten o'clock, would the army of London sightseers, be congregated as it were, to storm the entrance gate at that early hour; I think I am justified in saying, the probability is, they would not; would our constitutional friend, with the "Star and Garter" in his mind's eye, be found there? I think the very strong probability is, he would not. Our purely botanical friend, being one of the select or elect, which you like, would possess the talismanic "open sesame" without calling in to request the services of the portly janitor of those handsome gates; but, I think, the strong probability is that the generic type to which I have already alluded, and of which Adam was the founder, would be represented by more than one solitary individual. As a disciple of the great school of horticulture he could spend his annual holiday (not half-holiday as heretofore) broken, very possibly, in order to realise the full appreciation of the boon thus conferred, by a sojourn, about mid-day, to the "Rose and Crown," or the "Coach and Horses," to refresh the inner man, analyse his notes, and return, re-invigorated, to his work. Would it not be conferring a boon upon such a class—of which the bone and sinew of horticulture is composed—to allow them a before dinner, as well as after dinner, inspection of the gardens? Certainly, from my own experience, I will say that, for a detailed examination, even of the most superficial character of one-tenth part of the plants at Kew, the narrow limit of an afternoon is a complete absurdity. Kew Garden has been, is, and, I trust, will continue to be, an educational establishment. It has a purpose far higher to fulfil than the mere gratification of a host of cockney excursionists and sightseers, and in fulfilment of that purpose, I say distinctly, there is no practical reason why it should not be open to the public at ten o'clock in the morning. Do the Botanic Gardens at Edinburgh, at Glasnevin, and at Liverpool find that it is detrimental to the working of those institutions to open at an earlier hour than our national establishment? I think not. Have they found that admission at an earlier hour interferes with the routine work which is essential in all gardens? I think not. Surely the London public, who have enjoyed a longer and more effectual training than their provincial brethren, are not less cognisant of the rights of mine and thine! so as to compel the necessity of an attendant in every greenhouse on the place! The privilege of inspecting the gardens on a Sunday is limited to half the day, and rightly so; but I would ask, are all the staff in attendance on that day? I may be wrong, but I think not. Those who oppose the movement on the ground that the mens' time would be required to look after the public rather than the ordinary practical work of the place, estimate the good conduct of the London public at a standard far below what their experience ought to justify; on the contrary, it is a noteworthy fact that scarcely any appreciable damage has been done by visitors to these gardens during the last few years. Even supposing the opening of the houses earlier than at present should cause some inconvenience, surely the gardens and pleasure grounds at Kew require no stricter surveillance than the many other parks and public gardens of the metropolis. The suggestion made in an article on this subject, to which I have already adverted, namely, that that portion of the gardens known to nearly everybody as the pleasure grounds should be opened at ten o'clock, partakes of the nature of a compromise, and I feel sure the authorities at Kew will deem it quite unnecessary to adopt a half-measure; but, as has heretofore been their wont, come bravely to the front and meet the public wish; which is, in my opinion, neither unreasonable nor extravagant. Should a little additional expense be incurred, surely our national exchequer would be both willing and able to grant the same in the next year's estimates. My impression is strong, however, that beyond the increased remuneration to gate-porters and police for extra hours of duty, the additional expense would be little or nothing.

AN OLD KEWITE.

NOTES OF THE WEEK.

— MR. J. TRAHERNE MOGGRIDGE, writing from Meutone, informs us that both there and at Hyères the people speak of the extraordinary crops of fruit and grain, which they have had this summer; and the Olives still remain to attest the truth of this, the pale green, unripe berries, giving a new tint to the trees, the branches of which are in places dangerously strained by their weight.

— A POWERFUL organisation is, we hear, to be set on foot for opening Kew Gardens at an earlier hour on Sundays than at present. While Hampton Court Gardens are opened at ten or eleven in the morning, Kew Gardens are not opened until two o'clock in the afternoon, to the great annoyance of a large number of Londoners who go down every Sunday.

— MR. DAVISON, White Cross Nurseries, Hereford, writes to us to say that Mons. Thiers Rose is not sufficiently known or appreciated as a late autumn bloomer. It is much finer now in size and colour than at any other season. "We have recently cut (he says) from the Maunetti stock, blooms of this Rose 5 inches in diameter, and in colour a deep rich crimson, shading off to intense purple on the outer petals. I have (he adds) one now in a vase on my writing table, and nothing more exquisite in colour and fragrance has been cut during the whole season."

— THE Temple Gardens are just now well worth a visit. The Chrysanthemums are in bloom, and the turf, fresh and green for London, affords a cheerful relief from the bustle and noise of the busy streets. We notice that the old Elm near the fountain has been cut down, a circumstance not to be regretted, inasmuch as additional light and air are thus afforded to some promising young Planes which will be greatly benefited by the change. Two or three fine Catalpas here still retain their foliage, showing that this tree is well suited for town garden decoration.

— SOME very beautiful crosses and other designs, in silvery Immortelles, may now be seen in Covent Garden Market. They consist of large white Helichrysums, with which are associated bleached Grasses of different kinds, but more especially the common Hare's Tail (*Lignrus ovatus*), and different kinds of Quaking Grass (*Briza*), while, occasionally, the bright leaves of the Cape Silver Tree (*Leucodendron argenteum*) are employed in their construction with excellent effect.

— WITH reference to the wail about the degeneracy of young gardeners, which has existed for some time in the pages of some of our contemporaries, Mr. David Thomson writes to us to say, "I get first-rate fellows—far too good for the money they get." Our own impression is that there is no justification for writing of this kind, and that the young gardeners of the present day are in no sense inferior to those of any preceding time.

— WE have received from Mr. Peter Grieve excellent examples of a new seedling Pear, raised at Culford and named Lucy Grieve. In shape it is somewhat intermediate between William's Bon Chretien and Marie Louise, the flesh being white and agreeably perfumed like that of the Jargonelle. It is of excellent flavour and deserves to take a place amongst first class dessert Pears. We understand it is to be figured in the November number of the *Florist and Pomologist*.

— THE Chartometer or map-measurer, which we have just received from the inventor and manufacturer, Mr. Russel Morris, of High Street, Birmingham, is a very ingenious and useful instrument. We have carefully tested the accuracy of its measuring powers, and find that the distance between point and point on all maps laid down to a proper scale can be ascertained with the greatest nicety, however zig-zag or irregularly roundabout the road may be, from one given point to another. We shall give a more detailed notice of this contrivance in a future number.

— SEVERAL beautiful varieties of *Agnus Castus*, have been recently produced. *A. robusta paniculata* is a vigorous shrub, with widely-spreading branches; the foliage is soft to the touch, and the white flowers, tinged with pink, are developed in remarkably large panicles. Another variety, in some respects superior, has panicles which often attain the length of 16 inches or more. *A. C. macrostachya*, has flowers of a fine delicate blue, slightly tinged with lilac, which, placed near to *A. C. alba*, with purely white flowers, is said to produce a charming effect in the front line of shrubberies. These are described at length by M. Carrière in the *Revue Horticole*.

— WE have received from Mr. Divers, of Wierton House, Maidstone, a collection of different kinds of Grapes grown in the open air on a south wall, on which there is said to be a heavy crop. They consist of what is called American Cluster, a kind whose leaves become variegated in autumn, Black Hamburgh, Esperione, and Royal Muscadine. Of these the last is by far the best, being sweet, and altogether excellent, while the others (even the Esperione) are unripe and acid. It is the Chasselas de Fontainbleau of the French, and one of the best early outdoor Grapes in cultivation. Against

whitened walls we are of opinion that it might be brought to as great perfection in this country as it attains in France. We have also seen and tasted some fruit of the large Black Cluster, ripened at South Kensington, within a stone's throw from the Museum, the colour and flavour of which were excellent.

— MR. LASCELLES informs us that the curvilinear system of building wooden houses introduced by him, and illustrated in last week's number of THE GARDEN, is a patented invention. It is adapted for lean-to Vineries and plant houses against walls as well as for conservatories.

— MESSRS. HOOPER, of Covent Garden, have sent us a Begonia, the foliage of which is much more richly coloured than that of *B. Pearcei*, which is one of its parents. Above, the leaves of the new kind are velvety-green, marbled and veined with silvery-grey; below, they are of a rich crimson colour.

— THE Belladonna Lily, recently mentioned in our columns as a beautiful, hardy, and too much neglected plant, has flowered splendidly this season in an open border in the garden of the late Dr. Brand, St. Asaph, North Wales. The plants were even more vigorous than is usually seen in front of walls, and formed an attraction in the neighbourhood for several weeks.

— AMONG new or rare plants of interest to horticulturists, *Stewartia grandiflora* has been recently grown by MM. Thibaut and Keteleer, of Sceaux. This newly introduced Japanese species belongs to the same family as the Camellias and Gardenias. It is a shrub attaining occasionally the height of 6 feet or more. The flowers, which resemble those of a single Camellia, are pure white, and very large, the mass of stamens in the centre being of a rich and brilliant yellow. This fine shrub is perfectly hardy in the open air.

— A FEW months since Lord Skelmersdale, while visiting San Francisco, was struck with the fine finish of the wood-work Lick House, and also with the rich panelling of Laurel and Redwood in the Capitol at Sacramento. He remembered his admiration of the woods after his return to London, and, according to the *Californian Horticulturist*, sent for a collection for the adornment of his residence in London. The order was received by Messrs. Jacob Strable & Co., who are about to forward, by the barque Cuba, some of the finest specimens of Californian woods which the market affords.

— MANY of our most remarkable parks and gardens are what is conventionally termed show places. Windsor, Blenheim, Knowle, and many others that might be cited, are thrown open to the public. Lord Lyttelton, the owner of the beautiful park of Hagley, takes a very sensible view of the subject, in answering a complaint urged by a "Resident at Hagley," to the effect, that the summit of the highest of the Cleat Hills (adjoining the park), upon which an obelisk has been placed, is now rendered inaccessible to the public. He writes as follows:—"Some persons, I believe, think that in these days the owners of parks ought to allow all the world to go about all parts of them. Now, it is enough to say that this would have to depend on circumstances to some extent. If Hagley Park, with its peculiar conformation, its lovely dells, and recesses of all kinds, were thrown open to the whole of an enormous population, it would be tantamount to depriving my family of the use of most of it. As long as private property in parks is allowed I do not think this is reasonable." Lord Lyttelton then states the conditions laid down with reference to the admission of the public to the park, and, in remarking that the great expanse of Cleat Hill, with its famous scenery, is opened to all the world, he says, "I have been advised to take measures to have it enclosed. Nothing would induce me to do so, and the more people I see there the better I am pleased." With regard to Obelisk Hill, his lordship says it has been let for many years, like any other land, and if the tenant chooses to exercise his undoubted right to warn off trespassers, he can certainly not interfere with him. There are, however, two public highways on the hill, though not on the highest part of it. No one will gainsay Lord Lyttelton's plea for maintaining the privacy of some portions of Hagley Park; but in the case of Obelisk Hill, the reply hardly seems quite full and fair. We all know the paramount influence which landlords can, whenever they choose, exercise over tenants, and it seems evident enough that an arrangement might be effected by means of which ramblers in the bracing air of the Cleat Hills might be enabled to reach their highest point—a desideratum very generally felt. It is easy to say that two highways pass over the hill in question; but neither of them, as is acknowledged, pass near the top. Could not Lord Lyttelton, who is well known for his liberality, make a road right over the summit, leaving a space, say a quarter or half an acre, round about the obelisk, near which a few plain stone seats might be placed, and so gratify the longings of ramblers and sightseers; while, at the same time, by planting hedges along the road and round the small enclosure, the susceptibilities of the tenant, regarding privacy and trespass, would no longer be outraged by illegal intruders?

THE INDOOR GARDEN.

MESEMBRYANTHEMUMS.

THESE strictly belong to South Africa, where there may be found no fewer than 250 species or thereabouts. For the sake of convenience Haworth has divided Mesembryanthemums into forty-three sections and sub-sections. *M. debile* and *crassifolium*, though thought by some to be Australian species, nevertheless belong to the Cape, and probably went first to Australia from there or from this country. *M. cordifolium* (the lee plant), so well known in country districts, was sent to Kew a few years ago by Baron Mueller; but what more likely than that some plant-loving emigrant took it out to Australia as the Scotchman did the Thistle. The majority of Mesembryanthemums are easily grown, and make first-rate window and rock-work plants. Common garden soil suits them perfectly; the kinds represented in the accompanying illustrations, and their immediate congeners, may be placed among fancy sorts—little gems well worth cultivating on account of their quaintness and variety rather than as subjects for purposes of general decoration. For those who are fond of uncommon forms among plants, but who have little time or space to devote to their culture, these are plants well worth attention. *M. minimum* belongs to the sphaeroide section, a group

in which there are four others—*M. truncatulum*, *obconellum*, *muciforme*, and a new species at Kew, which is much larger than the others, and which has been named *M. truncatellum*. These plants never form a stem, and increase in size by bursting through the fleshy top when the outer part shrivels up, and the new formation takes its place. The flowers, which issue from the centre, are pale rose. Plants like these require to be potted in very sandy soil, and require to be well drained, when they will grow well. *M. testiculare*,

of which an illustration is given on another page, is a rare and beautiful plant, with a skin as smooth as silk, and very glaucous. It belongs to the sub-sphaeroide division. It is sometimes called *M. octophyllum*, but I never yet saw it with eight leaves. It is somewhat delicate, and should be potted in half silver sand, the other half being loam and brick rubbish, and should be kept near the glass in a dry house. *M. fissum* is closely related to this species, but it is more easily cultivated than *M. testiculare*. The most interesting of the Mesembryanthemums belonging to Haworth's section Ringente, so named on account of their resemblance to the jaws of animals, are *M. tigrinum* (Tiger's Chap), *M. lupinum* (Wolf's Chap), *M. felinum* (Cat's Chap), *M. erminum* (Rat's Chap), *M. murinum* (Mouse's Chap), and *M. mustellinum* (Weasel's Chap), all exceedingly interesting, and easily cultivated kinds; their flowers, which are all yellow, open in the afternoon. The next section, Scapigera, contains *M. caninum* (Dog's Chap), *M. aguinum* (Lamb's Chap), *M. vulpinum* (Fox's Chap), all of which have been cultivated for years. They form valuable plants for rock-work in summer, standing well out of doors in the south of England from May until October. They are easily propagated by pieces pulled or cut off and laid in the sun on moist sand, where they root freely in a few weeks, and often keep on flowering as though nothing had happened. For window decoration, and for general purposes, I have

found the following to be the most useful, free-flowering, and easiest grown:—

<i>Drooping Species.</i>					
M. <i>tricornum</i>	.	red.	M. <i>formosum</i>	.	red.
M. <i>diversifolium</i>	.	red.	M. <i>retroflexum</i>	.	red.
M. <i>Rossii</i>	.	red.	M. <i>imbricans</i>	.	red.
M. <i>curvifolium</i>	.	white.	M. <i>floribundum</i>	.	red.
M. <i>Blandum</i>	.	white.	M. <i>candens</i>	.	white.
M. <i>conspiciuum</i>	.	red.	M. <i>barbatum</i>	.	red.
M. <i>spectabile</i>	.	rose-red.	M. <i>polyanthum</i>	.	red.

<i>Erect Growing Sorts.</i>							
<i>M. stelligerum</i>	.	.	red.	<i>M. croceum</i>	.	.	yellow.
<i>M. striatum</i>	.	.	orange.	<i>M. caulescens</i>	.	.	rose.
<i>M. stipulaceum</i>	.	.	rose.	<i>M. roseum</i>	.	.	rose.
<i>M. corallium</i>	.	.	white.	<i>M. aurantiacum</i>	.	.	orange.

Of these, the first eight are strong growers; the next three moderately strong, and the last three slender kinds. These form a good selection, and may be readily increased by means of cuttings, struck in the open grounds in summer. In winter they should be kept tolerably dry and free from frost.

J. CROUCHER.

SHOW CASES FOR ORCHIDS.

BEING desirous of placing my Orchids, when in flower, where they could be enjoyed by others besides my gardener, I have constructed in my conservatory a large glass case, in which rock-work and Ferns have

been placed. The Orchid-pans being set in greenery, and the blocks hung above it, produce a very charming effect, delighting the whole household, the very servants coming continually to have a good look at what they term, "them beautiful flowers." But their glory lasted for a very short time. They began to spot in two or three days, and blooms that should have flourished for a month perished in a week. Those from the East India House drooped in 24 hours. As yet I have used no artificial heat, but the conservatory pipes pass through the case, and, when they are heated, a certain degree of warmth will be maintained. I

cannot, however, warm the Orchid case without warming, also, the whole conservatory, and this cannot safely be done for the present. The cause of the spotting and speedy perishing was, doubtless, damp. Could you, or any of your experienced readers suggest some cure for this evil? Or, if the present show case admits of no remedy, can any person from his own experience advise me in what manner I may set out the Orchids for show in or close to the conservatory, removing them for that purpose when in flower from the plant-houses, where no visitor can be persuaded to seek them. Whatever the plan, it is indispensable that, if they are to have a high temperature, they should be seen through glass, so that their admirers may gratify the eye without enduring a Turkish bath.

Moat Mount, Hendon.

EDWARD W. COX.

[Our correspondent has hit upon a want long felt among many who grow Orchids, and other tender exotic plants that require much heat and moisture. In the instance above cited, the flowers decay through moisture condensing upon them—more especially during the night time when any sudden change occurs in the external temperature. When this happens, condensation of moisture on the flowers is sure to be the result, unless the case employed is thoroughly ventilated. A moderately humid and warm atmosphere is rather favourable than otherwise to the duration of these flowers, provided there is plenty of fresh air allowed to continually enter the case; it is stagnant humidity which does the harm. Some years ago Mr. Diamond, then gardener at Green Boyd, Halifax, found some difficulty in growing *Anacathochili* on account of stagnant moisture; and to obviate this he

Mesembryanthemum minimum.

contrived a case, the sides and ends of which were covered with perforated zinc. This, while it prevented cold draughts, allowed a free circulation of air to enter from the general atmosphere of the stove in which it was placed, and we think our correspondent would find such a contrivance superior to an ordinary wooden case in many ways. Of course, the case not being heated is a serious drawback; for it is well known that, while warm moist air means genial humidity and health, cold moist air, especially if stagnant, means damp and decay, especially in the case of delicate flowers grown in a hot plant stove. The Orchid-houses in the Royal Horticultural Society's Garden at South Kensington are built alongside a cool glass-covered corridor, and the plants when in flower are staged on a bench or placed near to the corridor, from which they are conveniently seen by visitors, who are not inconvenienced by the heat and moisture; while, from a cultural point of view, the plants are protected from cold draughts caused by the continual opening and closing of the doors. A somewhat similar contrivance may be seen at the South Kensington Museum, where a cool Fernery extends past five or six large plate-glass windows, through which the graceful forms and fresh greenness of the Ferns are seen to great advantage. At the City of London Club, Old Broad Street, there are some charming little window conservatories, in which choice Ferns and foliage plants grow well, and in which some Orchids would succeed perfectly. We have often thought what charming effects might be obtained in a similar manner by constructing a little conservatory or large heated case alongside the drawing-room or library, and separated from them by a plate-glass partition, through which the bright tints of Orchids and other plants in flower, and the fresh greenery of Ferns, graceful Bamboos, or other elegant-growing plants might be seen, as desired by our correspondent, without having to take "a Turkish bath" at the same time. The conservatory, so-called, is in many cases an actual nuisance, expensive to keep, while it does not furnish a tithe of the enjoyment afforded by a little case fitted with the choicest flowers only, like that suggested above, which could be attended to by the gardener or his assistants in an unobtrusive manner either in the morning or evening. In the particular instance in question, a case with back and ends of wire gauze or perforated zinc would be a great improvement on an ordinary one of wood, and, if possible, it should be heated by a small coil of pipes independent of the conservatory in which it stands. The rock-work, with its drapery of Ferns and Selaginellas, must necessarily throw off a large quantity of moisture, and if the case cannot be heated, then it would be more conducive to the lasting beauty of the Orchids if they could be removed, and the greenery necessary to show off the flowers introduced in the shape of pot plants. By these means the atmosphere of the case could be kept much drier than at present, judging from our correspondent's statement, already given. We shall, however, be glad to hear from any horticulturist who has succeeded in overcoming difficulties of this kind.—B.]

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Impatiens repens.—This is a pretty little basket plant, with prostrate stems of a thick succulent character and delicate pink colour, clothed with small heart-shaped leaves, not unlike those of *Fuchsia procumbens* in form. The flowers are tubular, and of a bright golden-yellow colour, which contrasts forcibly with the delicate stems and fresh green of the leaves. In a warm temperature this makes a very ornate plant, and is well worth culture.—P.

Raising Ferns from Spores: H. B. C. Sow in well drained pots or pans tolerably firm with sandy peat. Set these in pans of water, so that the soil may keep moist; scatter the spores on the surface of the soil, cover with a pane of glass. Never water, as sufficient will be absorbed from the pan. Place in a somewhat shady position in a stove or warm Fernery.

Solanum pseudo-capsicum.—This is largely grown in many gardens as a pot plant, and it may interest some to know that it is perfectly hardy in many warm and sheltered positions. A plant on the west wall of the herbaceous ground at Kew is just now gay with its bright coloured fruit, and forms a shrub a yard or more in height. In some parts of Devon and Cornwall, this plant would rival the *Pyracantha* during the autumn months, if planted at the foot of a sunny wall.

The Ivory-veined Amaryllis (A. reticulata).—This is a very effective foliage plant, having broad oblong leaves fully a foot long, and of a rich velvety colour, while a broad white stripe runs down the centre of each, giving a highly distinctive appearance to the plant. This *Amaryllis* is just now in bloom at Kew, each scape bearing two or three flowers the size and shape of those of *A. Belladonna*, and of a delicate rosy colour, distinctly reticulate or netted with rosy-crenula. It well deserves culture, both as a foliage and flowering plant.—B.

Oncidium Kramerii.—Amongst Orchids, this is my favourite—not so much on account of the singularity of the blooms, as on account of the very abundant way in which they are produced. A plant with a few flower-spikes on it will bloom successively and incessantly for years. The blooms are produced from the apex of a long slender stem, and resemble a beautiful butterfly, both in form and colour, being provided with three upright narrow petals and a broad massive lower one, of rich substance, magnificently spotted with bright and dark golden-bronze, and handsomely fringed round the lower edge. It succeeds well in a stove temperature, in a mixture of peat, charcoal, and sphagnum.—J. MEER, *Cliftonville*.

A GARDEN ROSE AND ITS INHABITANTS.

WE will not call the Rose the Queen of flowers; we will avoid all the common-places of which it has been the subject, and over which it has triumphed. Let us look at it only, and say what we see. There is no country without Roses: from Sweden to the coasts of Africa, from Kamtschatka to Bengal, or on the mountains of Mexico; the Rose flourishes in all climates and in all soils; it is one of the grand prodigalities of Nature.

The Rose tree before which we now stop is covered with white blossoms. Others bear flowers, varying from the palest rose to the deepest crimson and purple, from the most delicate straw colour to the most brilliant yellow. Blue is the only colour Nature has refused it.

Pure blue is a privilege which, with some few exceptions, Nature only grants to the flowers of the fields and meadows. She is parsimonious in blue; blue is the colour of the heavens, and she only gives it to the poor, whom she loves above all others.

Botanists, who take no account of either colours or perfumes, pretend that double Roses are monsters. What shall we call the botanists? We will exchange a few words with them before we come to the end of this journey.

This Rose tree was once a wild Rose, or Eglantine, which, in some obscure corner of a wood, decked itself with little simple Rose, each composed of five petals. One day, its head and its arms were cut off; and then the skin of one of the stumps which it was allowed to retain was opened, and between the bark and the wood a little morsel of the bark of another Rose tree was insinuated, upon which was a scarcely perceptible bud. From that day all its strength, all its sap, all its life, have been consecrated to the nourishment of this bud. The wound is close, but the cicatrice may still be seen. This Eglantine bears no flowers of its own: it is a slave, who works for a haughty master. That beautiful tuft of leaves and flowers are not its flowers or its leaves.

But, observe! there is, upon the green stem, just below the graft, a Rose bud, which begins to peep out. That bud will become a branch; that branch will belong to it. Oh, then Nature will resume her rights; the tyrant above, the beautiful Rose tree, the cultivated Rose tree, will wait in vain for the tribute hitherto paid to him; the sap will no longer ascend to him—it will all be kept for this dear sucker; there is not too much for it. But the gardener has perceived this attempt at rebellion: he has cut off the pretender, and all is restored to order. A few days, however, after this, the Rose tree again appeared to languish; the brilliancy of the monarch was diminished; the foliage looked yellow and faded; and yet the stem of the Eglantine was shining and smooth. Seek for the cause. The poor slave is ingenious and obstinate: he has caused a shoot to glide along under the earth, and only allowed it to see the day at a distance from its parent. Go back two or three steps, and behind that Gilly-flower you will see a little Rose bush, growing in a shade and silence. It is like what its father was; like him it has flexible branches and narrow leaves. Wait a year and it will become an Eglantine. Rub its leaves, and you will find they exhale a Pine-apple odour, peculiar to one species of Eglantine. Such was its father when he had branches and leaves of his own. Here it is in bud; here it is in blossom.

But the despot we left yonder is dead, and died of a horrible death: he died of hunger. The revolted slave who supported him, has, for a length of time, conducted under ground, all his sap to his well-beloved offspring. That beautiful crown of double flowers is withered: he himself, the poor slave, is sick, and will soon die; for he has kept nothing for himself. But he dies free; he dies avenged. He leaves a strong, young, and vigorous offspring upon which the little Eglantine blossoms of the woods will burst forth next year.

Our white Rose tree is not in this situation. The Eglantine which bears and nourishes it appears to be resigned to its fate; indeed, we might even say it is proud of its slavery. There are other slaves in the world who have no wish to break their chains when they are well gilded. Our Eglantine seems to take pride in its beautiful crown.

But what emerald is that concealed in the heart of that Rose? The emerald is living; it is a cecenia; it is a flat, square insect, with hard wings, like those of a cockchafer, and brilliant as a precious stone. Turn it up; its under side is of a still more beautiful colour; it is another precious stone, more violet than the ruby, more red than the amethyst. The cecenia, or Rose beetle, lives scarcely anywhere but in Roses. A Rose is its house and its bed. It feeds on Roses. When it has eaten its house, it flies away in search of another, but it prefers White Roses to all the rest. If by chance you find it upon another Rose, which is rarely the case, neither its abode nor its bed are to its mind. It would inspire you with the same pity that you would feel for a ruined banker, obliged to dwell in the fourth story, and to eat soup and bouilli as his only

banquet. It feels sad and humiliated by it; but still, breathing creatures must live. There are people who resign themselves to a worse fate than this.

Twenty flies, of different species and colours, are to be found upon different parts of the Rose tree; but I pay no attention to them—they are there by chance. They travel as you do; they trifle as I do. I only take heed of the natives of the country; I shall meet with the others elsewhere. We are not yet ready to quit our Rose tree; for strange things are going on at this moment.

Where are you, my dear friend? I have no idea where; but I very much doubt if the country in which you are sojourning be as smiling as my Rose tree; and, particularly, whether the inhabitants be as handsome, brilliant, and happy as the inhabitants of my Rose tree. And is it nothing to see living beings happy? But, to a certainty, you are viewing nothing so extraordinary as that which I see at this moment.

At the extremities of the young shoots of the Rose tree are myriads of very small insects, of a reddish-green, which entirely cover the branch, and seem motionless; they are aphides or Vine-fretters, which are born within a line or two of the place where they now are, and which never venture to travel 1 inch in the course of their lives. They have a little proboscis, which they plunge into the epidermis of the branch, and by means of which they suck certain juices which nourish them. They will not eat the Rose tree. There are more than five hundred assembled upon 1 inch of the branch, and neither foliage nor branch seems to suffer much. Almost every plant is inhabited by aphides differing from those of others. Those of the Elder are of a velvety black; those of the Apricot are of a glossy black; those of the Oak are of a bronze colour; those of Gooseberry trees are like mother-of-pearl; upon the Absynthe they are spotted white and brown; on the field Sorrel, black and green; upon the Birch, black, and another shade of green; upon the Privet, of a yellowish-green; and upon the Pear tree, coffee-coloured.

All enjoy a life sufficiently calm. You scarcely ever see an insect of this kind who is vagabond enough to pass from one branch to another. They sometimes go so far as to make the tour of the branch they dwell upon; but everything leaves us to believe that this is only done in the effervescence of ill-regulated youth, or under the empire of some passion. These outbreaks are extremely rare. Some of these aphides, however, have wings; but these wings only come at a ripe age, and they do not abuse them. The only serious care that seems to occupy the life of the aphid is the changing of its clothes. It changes its skin, in fact, four times before it becomes a perfect aphid; something like us men who try on two or three characters before we fix upon one, although, in general, we preserve three during our whole lives—one which we exhibit, one which we fancy we have, and another which we really have.

When the aphides have finished changing their skins, there only remains one duty to fulfil, which is to multiply their species; but they take very little heed about that; they have not, as quadrupeds have, to suckle their young—as birds, to hatch their eggs—or, as other insects, to enclose them in a cavern with necessary aliments. The aphid produces its little ones whilst sucking its branch; and it never turns round to look at the offspring it has given birth to. If the mother shows but little anxiety for the little one, the little one only returns the same amount of filial love that it has received of maternal love. It sets out, descends below the rest, takes its rank, and plunges its little trunk into the green skin of the Rose tree. There issue thus about a hundred from a single mother, who all fall in regularly below their predecessors, and begin to eat. In ten or eleven days they change their skins four times; on the twelfth day, in their turn, they begin to produce little ones, who take their rank, and themselves become prolific towards the twelfth day from their birth. The aphides of the Poppy are more precocious; in seven or eight days they have changed their vestments four times, and enjoyed what I should call the happiness of being parents, if they were not quite indifferent about the matter.

But, my good friend, you will say, upon reading this passage of

my journey, there is an important deficiency here: you profess to describe the lives of these aphides, and you don't say a word of their loves or their nuptials. I have here, you will add, an immense advantage over you. I relate to you, of every nation, a thousand whimsical or curious ceremonies connected with marriage. Yes, my excellent friend, I may answer, I could remind you of the loves of those two spiders, which, when starting for my journey, I fell in with in the corner of my window; but my present business is only with aphides. Aphides are acquainted with neither love nor hymeneals: aphides eat and make little ones, exactly in the manner of Mother Gigogne, who so delighted our childhood. Nature has taken the fancy to free herself, with regard to aphides, from the general law of reproduction. Don't however, imagine that she shrinks from the difficulty on account of the smallness of these animals. There are other animals which can only be distinguished with the assistance of a microscope, which, in this respect, come within the general rule. Notwithstanding the admiration which the study of insects must excite, you must not let this admiration be exercised upon their greater or smaller size. Great and small are only such with relation to ourselves; and when we express astonishment at seeing a perfection in the organs of the invisible cheese-mite, equal to those of the ox or the elephant, it is a false feeling, arising from a false idea.

One of these aphides will produce nearly twenty young ones in the course of a day; that is to say, a volume ten or twelve times equal to its own body. A single aphid which, at the beginning of the warm weather, would bring into the world ninety aphides, which ninety, twelve days after, would each produce ninety more, would be, in the fifth generation, author of five billions, nine hundred and four millions, nine thousand aphides—which is a tolerable amount. Now, one aphid is, in a year, the source of twenty generations. I very much doubt whether there would be room for them upon all the trees and all the plants in the world. The whole earth would be given up to aphides; but this fecundity, of which there are so many examples in Nature, need not alarm us. One Poppy plant produces thirty-two thousand seeds, one Tobacco plant, three hundred and sixty thousand; each of these seeds producing in its turn thirty-two thousand, or three hundred thousand—would you not think that, at the end of five years the earth would be entirely covered with Tobacco and Poppies? A carp lays three hundred and fifty thousand eggs at once. But life and death are nothing but transformations. Death is the aliment of life. These aphides are the game that nourishes other insects, which in turn form the food of the birds we eat. Then we are returned to the elements, and serve as manure to the Grass and the flowers, which will produce and feed other aphides.

We need not go far to seek for the enemies of the aphides. Look! here, quite at his ease, on a Rose bud, is a little insect well known to children; it is shaped like a tortoise, and is about the size of a Pea. Naturalists call it a "coccinella," and children know it as the lady-bird. It is now innocent enough; but it has not always been so. Before it became possessed of its pretty form, and its polished shell of orange, yellow, black, or red, sprinkled with black or brown specks, it was a large, flat worm, with six feet, and of a dirty grey colour, marked with a few yellow spots. These worms, which issue from amber-coloured eggs, deposited by the female upon leaves, are no sooner born than they set out in search of aphides. When they have found a branch covered with game, they establish themselves in the midst of it, and are in want of no food till the moment they feel they are about to be transformed; then they attach themselves to some solitary leaf, and wait, in abstinence, till they become veritable lady-birds.

There would still be a superabundance of aphides if the lady-birds were their only enemies. But, do you not see, hovering over one of the Roses, a fly, whose two wings move so rapidly, that it appears motionless? You would not care to catch it, it so much resembles a bee, or, rather, a wasp. Its body is striped with yellow and black, but, instead of being round like the two insects you dread, it is remarkably flat; besides this, it has only two wings, and I do not believe that any two-winged fly has a sting. It does not

Mesembryanthemum testiculare (see p. 385).

seem to take any notice of the aphides which cover the branch near to it. It is a *puccenna*. It has forgotten the humility of its youth, when it had not its rich yellow and black vestments, or, more particularly, its wings. It was formerly a sort of shapeless worm, of a colour not at all striking, a dirty green, with a yellow stripe the whole length of its body. Placing itself upon a bed of game, this worm seizes the aphides, one after another, with a sort of hollow trident, through which it sucks them, taking particular care to reject the empty dry skin every time. One of these worms eats nearly an aphid a minute; as regards the aphides, the matter appears to be perfectly indifferent to them, not one of them is ever seen to make the least effort to avoid being eaten.

A Roman emperor, who found his end approaching, cried out, in allusion to the custom of decreeing an apotheosis to dead emperors: "I feel that I am becoming a god!" So there is a moment at which this worm feels that it is becoming a fly; and, like the lady-bird, it seeks a solitary place to prepare for this metamorphosis.

Here is a branch on which the aphides are only on one side; to-morrow there will be none at all; the reason of this is, that they are attacked by their most redoubtable enemy, an enemy which the learned and witty Reanmur called the Lion of the Pucerons. This is like the others, flat in form, and is of a cinnamon colour with citron-yellow stripes; it is much more voracious than the two other species of which we have spoken. If one of these worms, by mistake, happens to seize one of his brethren instead of an aphid so much the worse for his brother—it will eat him. It would be losing precious time to replace it upon a branch, and take an aphid instead of it. One can afford very little leisure for so much ceremony, when one has but a fortnight to eat all these fat aphides in! In fact, at the end of a fortnight, it forgets its appetite, and retires into a corner, shuts itself up in a shell of white silk, as large as a Pea, which it spins in a very short time. Three weeks afterwards, the shell opens, and there issues from it the most beautiful little creature you ever saw. It is a sort of large fly of a gay green colour, covered when it is settled, by long and large wings, of so fine a texture, that its body can be plainly seen through them. These wings, which are of a very pale green, present to the eye fibres, as it were, of a deeper green, which form a network more charming than that of the richest lace; on each side of the head is an eye of a fiery red colour, the splendour of which far surpasses that of precious stones.

The learned formerly found little bunches upon leaves, which excited their attention; these were stems as fine as hairs, supporting a small bud, white like themselves; at other times the buds were found open, like the chalice of a flower; the thing was declared to be a plant by the learned. The learned, however, were wrong; Reanmur made it clear that they were the eggs of that pretty fly, of which we have just spoken, before and after the birth of the worm which was afterwards to be transformed into a fly.

I was afraid but now, of seeing the aphides invade the whole earth; I at present begin to fear that there will not be aphides enough to feed all the insects to which they are assigned as game. Nature appears to have partaken of this second fear, and for this reason has suppressed the delays and formalities, ordinarily reputed necessary; aphides must be born, eat, and be eaten in a very few days.

But what is that black animal which is ascending the stem of the Rose tree? It is an ant; it climbs spirally, to avoid the thorns; there it is upon the branch that is covered by the aphides. Is this another enemy? Why, La Fontaine told you it fed upon worms and insects; there, it is upon them, but it does not devour them. As aphides eat, they secrete a sweet liquor, of which ants are very fond, and this one is come to regale itself—it is a little black milkmaid, who comes to milk some little green cows, which pasture in a meadow of the size of a Rose leaf.

There is a bee which has glided into a Rose; it is not long before it comes out again, and flies away; its hind feet are loaded with a yellow dust, which it has abstracted from the heart of the flower. That yellow dust, mixed with the honey which it disgorges, will be the paste destined for the worms which are to become young bees. Do not fancy, however, that this dust has no other destination. It is now time to speak of the loves of the Roses.

We will abstain from allusions to, as we said before, the apocryphal loves of the Rose and the butterfly. The butterfly who lights upon a Rose, seldom comes there for any other purpose than to deposit eggs; which will become caterpillars that will eat the Rose. The loves then, of which I will speak are real loves, and are the most charming in the world. Figure to yourself that all those Roses which bloom in the garden, pale purple or purple-violet, yellow or nasturtium colour, white, or mixed with purple and white, conceal from your eyes numbers of innocent loves.

The ancients placed Dryads and Hamadryads in trees; there are nymphs quite as charming in Roses. Let us go back to the Rose tree of the woods. Its flower is composed of five leaves or five

petals; in the middle are some delicate threads, supporting little yellow masses—these are the stamens; these threads surround a sort of little green egg, which is called an ovary, which contains the seed or grains. The grains are eggs, which the plants leave for the earth and the sun to hatch, as turtles do, when they deposit their eggs in the sand. The mass which surmounts the stamens is covered with that yellow dust with which the bee that has just disappeared over the wall had loaded its feet. Every grain of that dust is a skin which contains a much finer dust, which fecundates the pistil. When once the pistil fecundates, the nuptial bed is taken down—the leaves of the Rose fade and fall, one by one; the stamens become dry and disappear. The ovary enlarges, and becomes an oblong fruit of the shape of an Olive, green at first, then yellow, then orange, then scarlet; then, some day, the fruit bursts, and grains of a gold colour, containing eternal generations of Rose trees, fall upon the earth and there germinate. The double Rose is a coquette of an entirely unique species; you have read fairy tales, in which a magician changes into trees or flowers her rejected lovers; have we not, besides, in mythology, Daphne changed into a Laurel, Clytie into a Sunflower? Did not Narcissus and Adonis become flowers, to which they left their names? Well, every one of the Rose leaves (beyond five) which surround the nymph who dwells in the double Rose, is one of these lovers—each of the petals is made of one of the stamens that she had. Certain Roses are so double that they have not one stamen left, and then they never have any seeds.—"A Tour Round My Garden."

Old Seeds.—On a recent occasion, Mr. Niven, curator of the Botanic Gardens, Hull, lectured on "Seeds." He said they must look upon seeds as being nothing more than a matured ovum. The object of each seed was, of course, the perpetuation of the kind to which it belonged. There was a great deal of analogy between a seed and an egg. The outer coverings of seeds were not unfrequently beautiful when placed under the microscope. After giving a technical description of the outer coverings of seeds the lecturer proceeded to speak of their preservation. The egg, as all would know, had the power of vitality for a long time, and seeds would grow after being kept for a long period. He daresay most of them had heard of seeds that had been found with mummies having been sown and afterwards springing up, but such cases were not well authenticated. Farmers said that the Wheat known as Mummy Wheat was the same as that which was cultivated in Egypt thousands of years ago, but he thought it was only a popular fancy. He could scarcely say how long seeds would keep, but for their proper preservation they must be kept in Nature's own granary. In making railway embankments the soil that was turned out from 20 or 30 feet below the surface was often known in the following year to produce flowers, &c., that were at the present time unknown to the locality. The seeds had been deposited in the ground, and, therefore, kept in Nature's granary—kept away from the extremes of dryness and moisture, and from the action of light, and had consequently retained their vitality for an unknown period. To retain vitality four things were required, namely, moisture, heat, air, and electricity. One reason why seeds were placed in the ground was to preserve them from the action of light. The amount of heat required to support seed varied very much. Some plants known to them would vegetate with a heat slightly above freezing point, while other plants, such as the Palm, required a temperature of from 80° to 100°. At the freezing point vitality would not cease to exist in such, but it would become very low.

Parliament Square.—The necessity for the destruction of the shrubs and trees of the enclosures of Parliament Square, while the works of the railway company were being carried through them, has, according to the *Builder*, been but little required or compensated by the present flat arrangements of Grass-plats and beds, and the forest of surrounding lamps. Surely it would have been possible to have had raised beds of sufficient elevation for good shrubs to take root and grow, which would have formed admirable surroundings and backgrounds for the statuary presumably intended to be erected there; but which, however, will now have to be viewed in connection only with the prim formalities of "bedded-out flowers" one part of the year, and the empty bare earth the remainder. A little naturalness of shrub and tree is infinitely preferable to all this; and flowers then come in as pleasing adjuncts, but fail of effect when their repetition in profusion, and in set geometrical patterns, is the prevailing feature.

A New Grass.—*Ullalia japonica* is a perennial hardy species from Japan, with long variegated leaves. The flower-stems are from 3 to 1 feet high, very reed-like, and produce loose panicles of flowers; these panicles are hairy and erect until dried, when they become elegantly curled, closely resembling Ieh dien feathers. It is a remarkably elegant species.

THE FRUIT GARDEN.

ON RENOVATING NEGLECTED ESPALIER TREES.

HAVING an espalier Apple Tree of the sort called Court Pendu-plat, that bore well, but had grown out of shape, I thought I might improve its appearance, and in time get finer fruit, by having it furnished with an entirely new set of branches. I commenced operations in the spring of last year by sawing off the four lower tiers, leaving only the two upper ones their entire length, and taking off the others about 4 inches from the stem. In this manner I secured the produce of the two tiers that were allowed to remain, and from which a large proportion of the fruit had of late been obtained. From most of the stump ends of the removed branches shoots very soon appeared, more than sufficient to form the new branches; these, as they advanced, were secured to some stakes driven into the ground near the main stem. In the spring of this

Fig. 1.

year I removed the second tier in the same way, leaving the top tier only to produce fruit. New shoots have grown from the stem and on the shoots of last year, and the tree now appears as represented in fig. 1. I intend this winter to make my selection among the new branches, the produce of this year and last; and, at the winter pruning of 1875-6, the tree should appear as represented in fig. 2, at which time the two remaining branches, if the new are beginning to be productive, might be removed. The advantages of proceeding in this way are obvious; the tree never ceases to bear crops, though for a time they may not be as abundant as if the tree had not undergone the operation; and by the gradual renewal of the branches and maintaining in each tier a just proportion in their length and thickness, the production of quite a model espalier will reward your labour in a very few years. Whereas, had the whole been removed at one time, and nothing been left but the

Fig. 2.

stem, all the largest and best shoots would have appeared at the top, and a battle between the tree and its owner—between Nature and Art—would have to be carried on for several years, and little or no fruit would be produced. As regards the retention for a time of the highest tier, it would be well to denude them gradually of their spurs and shoots, proceeding in a direction from the stem towards their extremities, allowing by this process all the light possible to the new branches beneath. Then, when the time comes for their entire suppression, they might be cut short off, either close to the new top tier, or at their junction with the stem; in the latter case, two new leaders, proceeding from the excision, would leave the tree of the same height that it was before the process of renewal commenced.

B. S.

RIPENING PEARS OFF THE TREES.

It is difficult to make some persons believe that, as a general rule, Pears should not be permitted to ripen on the tree. Of course, sticklers "for Nature as a guide," will try to argue the question whenever it is presented in this form, but the proof is to be found in the difference in Pears ripened by the natural and unnatural processes, if we choose to class them as such. Winter Pears and Apples do

ripen finely after they are taken from the trees, but I hardly think it will be claimed that these same varieties would be of better quality if grown where the season was sufficiently extended to admit of full maturity upon the trees. Our northern varieties of these fruits when cultivated in a southern climate, do not show any improvement in consequence of the change; and, further, the pomologists of the south, as well as those of the north, advocate house-ripening of Pears and late Apples. There are, it is true, a few varieties of our best Pears which appear to retain their good qualities if allowed to mature on the tree, but those are exceptions to the general rule. But this is not conclusive evidence that they would not be better if gathered before perfectly ripe. Of course, this early gathering of Pears is nothing new to experienced pomologists, but the masses do not appear to know anything about it, hence their neglect of this very important part of Pear culture, and the consequent failure to secure excellent fruit. I am reminded of this by seeing early Pears in my neighbours' gardens and orchards, as well as wherever I happen to travel through the country, all left upon the trees until they fall with over-ripeness. It is no wonder that we hear complaints of rotting at the core with such noble varieties as Flemish Beauty and Clapp's Favourite. The first, in particular, will show a splendid exterior up to the last moment if left on the tree to ripen, while from the centre out to within an eighth of an inch of the rosy cheek is a mass of rottenness. Out of more than a thousand varieties of Pears grown by "Moore's Rural New Yorker," we did not find one which was not better in quality when ripened off the trees than on it. The chemical changes which take place in the fruit during what is termed ripening appear to be more perfect if retarded than when hastened, hence the benefits of gathering early and placing where the process will proceed slowly. We have many varieties which, if allowed to ripen on the tree, have a coarse gritty flesh, but become mellowed and softened, or, as the pomologist would say, "buttery," when ripened in the house.

When to Gather Pears.

It would be difficult to designate the exact time when any particular variety should be gathered, for it is the conditions which must govern in these matters, and they vary with the seasons even in the same locality. A little observation and experience will usually enable one to come near enough to be successful. When a few of the earliest matured on a tree begin to change colour or drop off, and the stems of those which are still green will part readily from the branch when lifted, it is time to gather all. Perhaps there is no surer method of determining maturity than the free parting of the fruit stem from the spur on which it grew. If the stem adheres so firmly that it will break, then the fruit is not sufficiently mature for gathering.

Preserving and Ripening.

In gathering, considerable care is required to prevent bruising, because Pears will not withstand as rough handling as Apples, for a bruise is usually followed by rapid decay. Every specimen should be picked by hand and laid into baskets, not dropped, as though they were cobble stones or Potatoes. When gathered, place in a cool room or cellar in baskets, boxes, or barrels, allowing free ventilation for two or three days; then pack in tight vessels, but not larger than barrels, leaving the heads open or merely laid on loosely for a week or two longer if the variety is a late one, and it is desirable to keep them as long as possible, remembering that slow ripening will bring out more fully the good qualities than rapid; consequently a very cool place is preferable to a warm one. If spread upon shelves in a light airy room or cellar, shrivelling and decay will soon destroy the best and longest-keeping sorts. I have found tight boxes, like the common cheese box or half-barrels, with light fitting covers, very handy and excellent for keeping early or late varieties. For winter sorts, like the Vicar of Winkfield, Laurence, and Duchesse, it is an excellent plan to wrap each specimen in tissue paper when packed away for one's own use. By an occasional examination of the top layer the condition may readily be determined, and when ripening is desired or delay is no longer safe, the specimens, or those wanted for immediate use, should be taken into a warm room—for instance, the kitchen closet—but still kept in a tight drawer or box. A week in such a position will increase the sugar in almost any variety, perhaps, fifty per cent. I know that some of our pomologists would smile at the idea of the Vicar of Winkfield Pear being a good dessert variety; but if they will start with well-grown specimens in the fall, keep them in a cool place until January, or even later, then ripen them up in a warm room slowly, they might find occasion to change their minds in regard to quality. But if ripened hastily it is poor enough and valuable only for cooking, and the same may be said of many other popular sorts. From long experience I have learned that to obtain a good crop of Pears is but half the battle; they often require careful manipulation in order to get the most satisfaction out of them, and equally as much skill as in the production.

The Best Covering for a Vine Border.—In answer to your correspondent (see p. 313), I would say that wood no doubt makes the best and cheapest covering, but shutters of it should not be made in the old imbricated way, as, when so constructed, they are too cumbersome and heavy. I have used wood covers, light and simply made, for many years, and they answer well. The boards are cut rather over a quarter of an inch in thickness, and of the lengths required; they are then nailed on to ribs lengthways, but the ribs are all scooped out, as here represented. The boards then become furrowed, and carry off the water easily. They are raised at the top on props or on flower pots, so as to give them an easy inclination towards the front and to allow air to circulate freely over the border

Scale, 1 inch to the foot.

below them. When the covers are taken off in spring they are gas-tarred over and put away one on the top of the other; used in this way, with care, a set of board covers will last for twenty years.—*WILLIAM CULVERWELL, Thorpe Perrow, Bedale.*

Prune Often.—As most persons do their pruning in the spring of the year, before other work fully engages their attention, this practice seems to have almost established itself without so much as a question as to its propriety in any other light than that of convenience, occupying leisure time, and getting the brush off the ground before it is otherwise occupied. But, assuming that this parcel of ground has been set apart for fruit raising, we will discuss the subject only in reference to this end. In young orchards, where the growth of the tree is the leading object, the early part of the spring is perhaps as good a time as any, but young trees should be pruned oftener than once a year, in order that the growth may be conducted in the desired direction. It is very improper to allow a thrifty young tree to make a full year's growth on one side only, and then, when spring comes, to rob it of all its progress; and this too often proves to be the case when pruning is done but once a year. For example, take a tree that has grown its branches heavily to one side. Cut back these branches in early spring, and, by the time the tree has fully commenced its summer's growths, you will find another leader already advancing in the same direction, which, if left alone, will again lead the principal part of the year's growth to be cut away by the saw and lost. To avoid this, every young orchard should be carefully examined by some capable person several times throughout the growing season, those false leaders headed back, and a uniform growth encouraged until the proper direction has been given to the growth of the young tree. In order that the great importance of this repeated pruning may be felt by growers, I will enumerate some of the benefits attending its neglect, which are of so common occurrence that you cannot fail to notice them. Prune often and carefully; shape your trees according to the most approved plans, and avoid the necessity of losing the growth of your trees by heavy pruning, or causing disease and "sores" by severe pruning. Thinning for the present crop, then, ought to be done in June, or after the fruit has set, for which I give the following reason. A tree in vigorous growth of wood seldom produces much fruit, and, if pruned while it is yet dormant, the propelling current which the roots send forth, being confined to a reduced number of branches, accelerates its growth of wood, and causes a greater proportion of blossoms to wither without setting fruit; but, if pruned after the fruit has fairly set and is beginning to draw upon the sap of the tree, this increase of force will at once supply the want, and a good healthy crop will be secured. In conclusion, I would say:—For a growth of wood, prune while dormant. For a present crop, prune in June; and for a prospective crop, late in August or first of September.—*Rural.*

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Up a Tree.—There is a Currant bush at Rochester, N.H., which, though growing among the branches of an Elm 20 feet from the ground, has borne well for more than a dozen years.

Orchard-house Plums.—Amongst the orchard-house trees in Mr. Wilson's garden at Heatherbank, is a pot-tree of Che's Golden-Drop Plum which is quite remarkable. The entire crop brought to maturity was 212 fruits. It should be added that these are not dry, starveling fruits, but full-sized, succulent, high-flavoured examples of the variety, which is well-known to be one of the best Plums in cultivation.—*Floral.*

Fruit Trees with Low Branches.—Train your Pear trees for garden use that they will branch at a distance of 1 or 2 feet from the ground. The advantages are as follows:—1. It is easy to trim. 2. It is easy to gather the fruit. 3. Falling fruit is little injured. 4. The branches being sturdy, will not be strained by great weight of fruit. 5. Soil will be kept moist. 6. The trunk will be protected from the scorching sun. 7. Trees thus trained are more beautiful.—*Horticulturalist.*

THE CHELSEA BOTANIC GARDEN.

Few London gardens are better worth visiting than this. The exact date of its formation does not appear to be precisely known, but it was, doubtless, a garden of some note in Gerard and Parkinson's time. It is situated in one of the oldest parts of Chelsea, on the banks of the Thames, from which it is now separated by the new embankment. It was presented by Sir Hans Sloane to the Apothecaries' Company sometime about the latter end of the seventeenth century, and on the garden walls near the entrance gate, we find the inscription, "*Hortus Botanicus Societatis Pharmaceuticæ Londinensis, 1684*," a date probably indicating when the walls were finished; for we have ample proof that the garden existed long before that time. Independently, however, of its historical associations, the garden is well worth notice on account of the fine collection of medicinal plants which it contains. In the centre is a circular basin surrounded by rock-work, well clad with hardy plants and creepers; here, too, are planted masses of Yuccas, which are extremely effective when in bloom in summer. In the tank, white Water Lilies grow and flower as freely as if in a clear stream miles away from the dust and smoke. I have before alluded to the readiness with which this and other beautiful aquatics luxuriate in town gardens, a fact worth the remembrance of those who have charge of the ornamental waters in our parks. If I recollect rightly, Battersea is the only park near London in which aquatics are grown, and even there their cultivation might be extended with advantage. All who have seen the interesting pond devoted to aquatic plants in the Botanic Gardens at Edinburgh, where the fragrant *Aponogeton distachyon*, pearly Water Lilies, and scores of other rare or beautiful water or marsh plants are grown in perfection, will readily agree that they deserve more general attention than they at present receive in our gardens, both public and private. In the Chelsea gardens there is a good collection of herbaceous plants, more especially those belonging to the Umbelliferous order, and also of hardy bulbs. Among Yuccas, too, I noticed fine specimens of *Y. flaccida*, *Y. gloriosa*, and *Y. recurvata*, all kinds well adapted for town gardens, to which they give a kind of semi-tropical appearance. Among trees, the old Cedar of Lebanon, which has served as a conspicuous landmark from the river for so many years, now shows symptoms of decay, a misfortune, doubtless, in part, attributable to loss of moisture at the root, occasioned by the formation of the new embankment. This fine old remnant of bygone days was, probably, in its prime in Elizabeth's time, when Westminster was comparatively a village separated from the city by green fields, and when gardens and orchards existed in Holborn, Long Acre, and all along between the Strand and the river. The companion Yew to the one now standing died some years since. There is also a splendid Plane tree at one corner of the garden still in vigorous health; and among smaller trees are good examples of Mulberries, *Broussonetia papyrifera*, and *Koeleuteria paniculata*, the last having produced here ripe fruit, a somewhat rare occurrence in this country. Of this tree there is a specimen at Linden House, Tarnham Green, nearly 50 feet in height. The Maiden-hair tree (*Salisburia adiantifolia*) grows tolerably well at Chelsea; while, on an old wall, is a well-developed Pomegranate, which covers a space of 30 or 40 feet with fresh green foliage. *Clematis vitalba* may be seen here clambering up some of the trees to a height of 20 feet, and during the flowering season wreathing them with snowy blossoms. The Wistaria, which is one of our best balcony and portico plants, succeeds admirably here; of this there is a specimen growing in the form of a bush on the open lawn in the Jardin des Plantes at Paris, and I have also seen it grown in that way with good effect in this country. The curator's residence is pleasingly draped with Ivy, not closely trimmed, but growing in a natural manner—here nestling close to the wall, then hanging in graceful masses, concealing the unsightly asperities of the builder. Green and variegated Ives are here intermixed, and, to add to the effect, patches of the variegated *Euonymus alatus* like burnished silver among the deeper green of the Ivy; and here and there, too, are brilliant scarlet clusters of fruit furnished by *Pyracantha japonica*. The new Japan Creeper (*Ampelopsis tricuspidata*) may also be seen here clinging close to the masonry—even closer than Ivy itself, and its leaves are now of a beautiful rich bronzy-crimson. In a convenient little propagating-house here, we noted two or three of the rarer *Selaginellas* growing freely, and at one end of the bed the old *Torenia asiatica* was blooming freely. A plant or two of the small white-flowered *Passiflora foetida* is worth notice on account of the great beauty of the fresh green mossy involucre which surrounds the base of its apple-green fruits; in a small state this plant is very interesting. This house is devoted to the reproduction of such tender plants as are required for the larger houses, and appears to be well fitted for its purpose, although limited as regards size. It is sunk two or three steps below the ground level, a position which is warmer and more moist and genial than one wholly above ground. One of the

houses on the west side of the garden is devoted to hardy and half-hardy decorative plants, among which may be found grand masses of the rarer British and North American Ferns, including *Osmundas*, and some of the best forms of Lady Ferns. These are planted out on artificial rock-work, which, in places, is carpeted with the fresh green Cornish Moneywort (*Sibthorpia europæa*), and other dwarf trailing plants. The narrow-leaved *Ophiopogon jaburum* does better in this garden than in any other with which I am acquainted, producing annually an abundance of bright purplish-blue Muscari-like flowers. With these are associated some nice bushy specimens of *Skimmia japonica* and *S. oblata*, both profusely covered with bright scarlet berries. In the large oblong span-roof house, near the centre of the garden, is a splendid specimen of *Monstera deliciosa*, a tropical fruit-bearing plant, rarely seen except at Kew, Chatsworth, or similar great places. This plant is of large size and is growing over a tank, into which its long thong-like roots descend in quest of moisture. It is now bearing several fruits in different stages of maturity. The plant itself is tolerably well known, as it has been frequently used in the London parks as a sub-tropical plant during the past few years, and a few weeks ago we alluded to a specimen growing and flowering vigorously in a large tub in front of a shop in Lowndes Square, where its singularly slit leaves and great white flowers attracted considerable attention from passers-by. A large span-roofed house, to the right of the curator's residence, contains some very interesting plants. Here, as elsewhere, are some fine masses of the blue-flowered *Ophiopogon*, a fine specimen of the elegant light green *Bambusa gracilis*, one of the most pleasing of all foliage plants for a cool conservatory or winter garden; while at one end of the house is a plant of *Ruscus androgynus*, the young shoots of which resemble *Asparagus*; its great pinnate coriaceous leaves last for several months in a drawing-room vase, if washed occasionally in clean water to clear them from dust. The front division of this house contains an interesting collection of *Agaves*, *Aloes*, *Gasterias*, *Hawarthias*, and other rare and curious succulent plants, among which there is a fine plant of *Aloe fruticosa*; and here also the orange-striped *Abutilon striatum* flowers freely. Associated with these are also fine masses of *Crassula lactea*, which is one of the best of all winter-blooming succulents. It grows freely in a cool greenhouse, or even in a window, and well deserves a place in the most select collection of decorative plants. To the west of the curator's residence is another span-roofed house, also planted in a natural and artistic way. The back wall is covered with *Picus repens*, which occasionally sports into a large-leaved form closely resembling that known as *P. barbata* in some gardens. Here is also a good specimen of *Dicksonia medullaris*, with its characteristic black rachis and ample fronds; and the great mealy-leaved *Aralia papyrifera* produces gigantic leaves in this house, some of them being 2 and 3 feet in diameter, and of great substance. The recesses in the rock-work are densely carpeted with fresh green *Selaginella* and small Ferns, while from the roof hang masses of the pale blue *Plumbago capensis*, laden with great clusters of its beautiful but somewhat fugacious flowers. The planting-out system, as here adopted in two or three of the houses, well deserves attention, as much less trouble and expense suffice to keep the whole in perfect order than are required where plants of all kinds are grown in pots. Even the saving of time in watering alone is a consideration here as well as in most other places, and there is no comparison between strong-growing subjects when planted out and when cramped in pots.

B.

Keeping Nuts.—Mr. Laxton, of Stamford, describes, in the *Journal of Horticulture*, a simple method of keeping Nuts. "I have sent you a sample of Cob Nuts which were gathered dry last October, spread out in the sun for a few hours with the husks on, and then packed in a box in layers with half-rotted cocoa refuse about as moist as ordinary petting soil; the whole well pressed down as packed, and kept in a cool wine cellar. I have followed this plan successfully for several years, and have found the flavour of the Nuts so preserved to be excellent. When they are required for use all that is necessary is to take out the quantity desired, and again press down closely the remainder. The Nuts, when taken out should be slightly dried in the air, and the refuse will then shake out and leave the Nuts clean and equal to those fresh gathered. Walnuts should be husked and dried for a somewhat longer period in the sun before being packed. Nuts without the cocoa refuse, but otherwise similarly and concurrently treated as the sample sent you, are now all bad. It is advisable not to have to refuse too moist, as, on one occasion, from this cause, I found a perfect forest of miniature Filbert and Walnut trees in my cellar in the spring after the Nuts were stored, the whole having vegetated at the growing period. The method is cleanly, and the refuse does not impart an earthy taste, as in the case of Nuts kept in the ground."

THE KITCHEN GARDEN.

POTATO CULTURE IN THE NORTH OF ENGLAND.

THE whole of my Potatoes were taken up this year by the middle of September. Last year I used Fowler's patent manure and long litter, which produced good crops tolerably free from disease. This year I have used long litter and a sprinkling of Gibbs's guano; but, although I have had excellent crops, the roots did not derive much benefit from the guano, on account of the severe drought which prevailed for about sixteen weeks. I did not plant until my usual time (the first week in April), and then only first early varieties, such as *Mona's Pride* and *Headley's Nonpareil*; all my other varieties were planted from the middle to the end of April, which is considered in Yorkshire the best time. Experienced Potato growers always hold that nothing can grow until there is natural heat in the land, and they are right; the late-planted varieties escaped being cut down by the severe frosts which occurred on the evenings of the 16th and 17th of May. My early varieties, along with my neighbours', were cut down, and, consequently, yielded smaller tubers than usual. In the northern counties we are never safe from frosts until after the 20th of May. It is not generally known that *Headley's Nonpareil* (one of the finest-flavoured Potatoes known) is an early variety, coming into use soon after *Mona's Pride* and other first early varieties. There are many early varieties with purple sprouts, such as *Myatt's Prolific*, *Rivers's Royal Ashleaf*, &c., which are classed as first earlies, but I never yet found any of the purple-sprouted Kidneys to produce a dish of Potatoes so early as the white-sprouted ones, both sorts being treated alike as to the day of planting, and having the sprouts also of about an equal length when planted. The length of the sprout, at planting time, has a great deal to do with early production—for instance, plant the old *Ashleaf* or *Mona's Pride*, with their white sprouts only just peeping from their eyes, and plant *Myatt's Prolific* on the same day with well-developed sprouts, about an inch long, well hardened and greened, so that you can roll them about without fear of breaking off the sprouts, and you will find *Myatt's Prolific* ready for eating, before the white-sprouted *Ashleaf* kinds. Plant them both on one day, with sprouts of an equal length, both hardened alike, both having received the same treatment, and you will find the white-sprouted *Ashleaf* the earliest by a fortnight. I find *Headley's Nonpareil*, which is related to the *Lapstone*, to be about as early as *Rivers's Royal Ashleaf*. *Headley's* can be eaten from August to February, about which time it begins to sprout freely, and seed of it then wants exposure to keep the sprouts from getting too long; for, it is an ascertained fact, that none of the Kidney section, whether of the early or late varieties, ever do well for a crop if the first sprout is lost, either by accident or design. Round Potatoes will bear rougher treatment than Kidneys; they may be sprouted without suffering so much, but it is always wise to secure the first sprouts, which are much stronger than those that appear afterwards—better haulm, and a heavier crop is the result. This year I have lifted fine crops of the America varieties quite free from disease. The *Early Rose*, *Late Rose*, and *Vermont Beauty*, are really good, and worthy of a place in the best gardens. *King of the Earlies* and *Climax* are the best in point of form, but the flesh of both is often hard and flinty; they are sorts that will not suit the English palate. *Climax* is often much diseased, but, *King of the Earlies* is nearly always lifted in a healthy state. In Yorkshire the Potato crops are good, a few kinds only being slightly diseased. In Worcestershire the disease has shown itself somewhat plentifully, and many growers are selling their Potatoes as fast as possible; in some cases at 6s. a bag. The *Lapstone* section, especially the late sorts, always commence supertuberating first; the quality of the crop is then injured, and the tubers, instead of being mealy, become hard and flinty. The second earlies of the *Lapstone* section are therefore the best kinds to grow, as they ripen by the end of July, or very early in August, before autumnal rains set in, and before disease begins to show itself. The best sorts proved here this season, have been *Early Rose*, *Late Rose*, and *Vermont Beauty*, all American red varieties, the last yielding a heavy crop. Amongst the *Lapstone* section, *Headley's Nonpareil* and *Beaconsfield* have been good, both ripening off by the end of July. A round white variety which has been grown in this district upwards of seventy years, called the *Old American*, has yielded a very good crop free from disease; it is of fine healthy quality, its flesh is white, and it ripens by the end of July. Although it has been grown for so many years, it is still as vigorous as ever, completely upsetting, in this respect, the wearing-out theory. Indeed, the original *Lapstone* at Jervaux Abbey is in no respect impaired in health, although the seed from which it is grown has never been changed for thirty years. This year, I grew 2 pounds of *Vermont Beauty*, and the crop, when lifted, weighed 64 pounds of very fine Potatoes—handsome and good. The tubers were of large size, the

heaviest weighing 1 pound 6 ounces; they are rough in the skin, which is a certain sign that a Potato is mealy; they become ripe enough to be lifted early in August, before disease sets in. Those who wish for a higher class Potato must grow the Lapstone section, in which may be enumerated Haigh's Seedling (Cobbler's Lapstone), Yorkshire Hero, Pebble White or Crystal Palace, Headley's Nonpareil, Huntingdon Kidney, Perfection, Rixton Pippin, Ashtop Fluke, Taylor's Yorkshire Hybrid, Beaconsfield, and Taylor's Alexandra Kidney (not yet sent out). These are all good croppers, but subject to disease. Headley's Nonpareil, and Beaconsfield, are amongst the best, and also the two earliest. There is another class of Potatoes which, on account of their vigorous haulm, are only fit for field culture. These consist of Red Skin Flourball, Victorias, the Red Fluke, and others, all, however, profitable in the market.

As regards culture, I find Potatoes to succeed best where the land has been manured and roughly turned up in the autumn, so as to leave it exposed to the mellowing influence of frost. Early in the spring it should be forked over again, in order that the manure may become thoroughly incorporated with it. Round Potatoes may be planted with the dibble, but Kidneys do best planted in trenches about 4 inches deep; the sets being 1 foot apart, and the rows 2 feet asunder; place some straw litter over the set to act as drainage, and then add a slight sprinkling of guano, sulphate of ammonia, nitrate of soda, or, indeed, any of the new artificial manures, but good guano is, I think, the best; then rake all level. As far as expedition is concerned, no tool is so good for this purpose as a common wooden rake. I plant my late and second early kinds in March, if the weather is favourable; I never plant first earlies until the first week in April, should they begin to peep through the soil, I cover them up with the hoe, and keep them covered as long as I can, in order to escape frost. I do not advise very early planting with the view of getting an early crop, except where one happens to have a nice snug warm nook, well sheltered from the north by a wall or high hedge. A cultivator in the Isle of Man produces early Potatoes as follows:—Early in November he removes his Cucumber frames to an eligible situation. He mixes up the old hot-bed manure with some fine soil, fills the frames about half-full of this compost and then plants a few nicely sprouted Mona's Pride Kidney; he covers up every night with mats, and on favourable days gives a little air. In February the haulm gets long, being drawn by the glass, when he prunes it back considerably, and in March the tubers are ready for eating. Let us now examine the different varieties of Potatoes grown here, this year, seriatim.

Mona's Pride.—This Ashleafed variety, with a white sprout, is now well known, and, if the true sort is obtained, it is one of the best of croppers, well flavoured, and mealy. It was a little diseased this season, and the tubers were small, having been cut down by frost. The haulm died down naturally in July.

Early May.—This is a very early variety, with white sprouts, prolific and good, each root yielding from twenty to twenty-six tubers. Both this and the preceding have shining green leaves, and are distinct from the Myatt's strain. It was cut down by frost; still it yielded a very nice crop. Haulm dead by the end of July.

Vermont Beauty or Brownhill Beauty.—This is a new American variety, that was sent out by English seedsmen this spring. The tubers cluster together near the base of the stem and the surface of the soil, yet not so near as to protrude and become green. The haulm, even when grown in rich soil, does not exceed 18 inches in height. It is a second white-fleshed early of excellent quality, and boils very mealy—a grand variety for roasting as well as boiling. It obtained a first-class certificate, after being grown for trial, at Chiswick.

Early Rose.—This is another American variety, now pretty well known, and one which produces excellent crops in most soils. Its flesh is white, and, when ripe, quite mealy. The haulm is short, and it is a good cropper, coming in soon after the Ashtop section; it is a variety that does not readily become diseased, and, on this account, I consider it valuable.

American late Rose.—This is an excellent sort, and a good cropper, from eight to ten large tubers being often produced by one root, and often more, some of them weighing upwards of 1 lb. each. The produce of each root averages from 3 to 3½ lbs.; it is a second early, and can be lifted for storing by the middle of August. It has obtained a first-class certificate.

Red Fluke.—This Potato grew away nicely with me up to the first week in August, when I thought it was going to ripen off, but no sooner had rain come, than the haulm again began to grow, and it is now from 5 to 6 feet long, and the crop is supertuberating. I have lifted a root this day (7th October), and have found forty Potatoes attached to it, weighing 4 lbs. Half of them, however, were deformed and unshapely.

Alma Kidney.—This nice white Kidney, was planted on the 20th of April, and escaped being cut down by frost in May. It quickly forms tubers, of which I took up a dish on the 29th of June. The haulm is of moderate growth, and the tubers are formed at the ends of wiry-looking roots, but do not come through the soil; it is of good quality, free this year from disease, and a moderate cropper.

Headley's Nonpareil.—I find this to be one of the best of early white Kidneys. I planted it the first week in April, and took up a boiling on the 22nd of June, when the tubers were as large as a hen's egg. The haulm is not unlike that of Rivers's Royal Ashleaf. It boils white and mealy, and possesses the best flavour of any Potato grown. It belongs, as I have said, to the Lapstone section, of which it is the earliest. It is a moderate cropper, and invaluable for winter use from August up to February. The tubers, which are smooth and handsome, do not grow to a very large size, but there are plenty of them at a root.

Yorkshire Hero.—This is another of the Lapstone section, and a good cropper in light sandy land, but in many places subject to disease. It is of the finest form and remarkably good in flavour, mealy and natty. With me it has supertuberated, and is a little diseased.

Rixton Pippin.—This is one of the newer varieties belonging to the Lapstone section; its tubers are large, smooth, and handsome, mealy and nutty in flavour. It is slightly subject to disease, as, indeed, nearly all the Lapstone section is; each root produces, on an average, from 3 to 3½ pounds. I have now grown it for four years and find it to be good and an excellent keeper.

Alexandra Kidney.—This is a cross between the Round Ashtop, or Fox's Seedling, and the Yorkshire Hero. Its tubers, which are well flavoured and handsome, ripen in August.

Red-skinned Flourball.—This is a late variety, liable to supertuberate, but excellent in winter and spring. With me, it has only slightly diseased this season. It is best suited for field culture.

Rivers' Royal Ashleaf.—This comes into use in Yorkshire about ten days or a fortnight after the first earlies, and it is rarely diseased. Its only fault is being yellow-fleshed.

After having proved all the above-named varieties, and others, for a small collection, I would recommend the following: Alma Kidney, Early May, and Mona's Pride, for the first earlies; Early Rose and Headley's Nonpareil, for succession and for autumn and winter use; the Late Rose, Vermont Beauty, Beaconsfield, and Rixton Pippin, all kinds that are sure to give satisfaction.

HENRY TAYLOR.

The two Carpets.—About three years ago I purchased an old carpet to place in my studio, as I call an apartment tolerably well furnished, in which I sometimes shut myself up, to prevent interruption whilst I am doing nothing. This carpet represents foliage of a sombre green, strewn over with large red flowers. Yesterday my eyes fell upon my carpet, and I perceived that the colours were becoming very faint, that the green was getting of a very dingy hue, that the red was faded in a deplorable manner, and that the wool was worn off, and showed the string over the whole space that led from the door to the window, and from the window to my arm-chair in the chimney corner. That is not all; whilst moving an enormous and heavy table of carved wood, I made a rent in the carpet. All this disturbed me so much, that I immediately had the rent repaired, but I could neither restore freshness to the leaves nor brilliancy to the red flowers. But this morning, whilst walking round my garden, I stopped before the Grass-plot which is nearly in the centre of it. Now here, said I, is just such a carpet as I like, always fresh, always handsome, always rich. It cost me sixty pounds of Grass seeds, at 2d. per pound, that is to say 12s., and it is about the same age as that in my closet, which cost me £12 10s. That which cost £12 10s. has undergone sad changes; it is now poor, and becoming poorer every day, in its tarnished splendour, threadbare, disgraceful and patched; whilst this before me becomes every year more beautiful, more green, more tufted. And with what profuseness of beauty it changes and renews itself! In spring it is of a pale green, strewn over with small white Daisies and a few Violets. Shortly after, the green becomes deeper, and the Daisies are replaced by glossy Buttercups. To the Buttercups succeed red and white Trefoil. In the autumn my carpet assumes a yellow tint, and instead of the red and white Trefoil, it is sprinkled with Colchicums, which spring from the earth like violet-coloured Lilies. In winter its white snow dazzles the eyes, as it has been danced and walked over. Then, although in the spring, as well as the autumn, it is a little worn and ragged, it puts itself to rights in such a manner that we cannot perceive its wounds, or even its scars: whilst my other carpet remains there with its eternal red flowers, which become more ugly every day, and with its badly-mended rents.—ALPHONSE KARR.

RIVER-SIDE GARDENS.

IN a river and streamlet-seamed country, like the British Isles, the opportunities for making charming and most varied river-side gardens are many, and should be taken more advantage of. Some of the most beautiful scenes in British gardens are those on the banks of rivers, as, for example, those at Curraghmore, Cliveden, Bothwell Castle, and many other gardens; indeed, they might be named on the banks of almost every British river or stream. It behoves us, then, to bear in mind a few principles in dealing with this description of garden scenery, never forgetting, however, that the variety of situation and local peculiarities are so infinite that novel combinations may be made in almost every instance. As a case where little or no attempt has been made to combine garden with river beauty we may instance Kew. An important point is also well illustrated at Kew, and that is the mistake of forming a poorly-designed artificial lake near a nobler river. Where a finer river exists

their beauty. There is a river Thames in Canada West, on the banks of which the writer saw the only tree pictures he met with in that part of America. That group of trees, seen across the busy reach of water, would never have attained half their full spread of branches had they been crowded in a wood; nor could we, in that case, see the noble wall of foliage standing defined against the blue sky, swelling forth into beautiful rounded, yet varied, forms, unrestrained only by the powers of growth of each tree. In fact, the river gives us a precious vista and tree picture-gallery, so to say, which cannot be foolishly destroyed by being dotted over with trees and shrubs at regular intervals; however, we are not absolved from the necessity of securing those quiet open carpets of turf, which are so essential elsewhere. In planting, it is the fashion to plant certain trees near rivers, and no doubt they are suitable for the position, but there should be no such limitation. In many cases

River-side Garden Scenery.

the wise gardener will create as much beauty on its banks as is possible, and not attempt to form within a stone's-throw an artificial pond, which, except thoroughly well done, must look more absurd than usual beside the natural water. Sometimes, in the case of a small river or stream, improvement may be made by widening the bed, or by so damming it that a handsome sheet of water is formed; but this is quite a different proceeding from what has been done at Kew, where a very poor piece of artificial water has been made on the banks of the Thames. River-banks offer grand opportunities to the planter; even Nature herself takes advantage of them to show some of her finest sylvan effects. Thus, in parts of North America, where the trees stand thickly, it is on the banks of rivers you will frequently find the finest trees and the most beautiful tree pictures. This is not because there is abundant water and rich food thereon; there is space for the trees to develop, and a foreground which permits us to see

there is high and dry ground, as well as moist, near the river, and where this is the case, most kinds of hardy trees may be grown successfully. There are, however, some neglected and rare trees, like the Nyssas, which would thrive well very near the water; and there is some reason to fear our system of thoroughly draining the land will some day leave us with only the river-side as a suitable position for the many trees that grow naturally best in a moist soil; of such there are a great many more than is generally supposed. The views in river-bank plantations are often very fine, if they are well managed and kept open; frequently the removal of a few trees may open a charming vista. Mr. Fleming has at Cliveden made some delightful ones. There is no better position than the river-side for the more picturesque arrangements of hardy plants; and, as a rule, all in the neighbourhood of a river or stream should be treated in a purely informal and easy style. All walks by the margin should be avoided as much as possible.

OUR RAILWAY BANKS AND SLOPES.

SUGGESTIONS FOR TURNING THEM TO A MORE PROFITABLE ACCOUNT.

[As you have lately published (see p. 265) a note from Mr. Moggridge on the planting of railway embankments, I venture to send you a copy of a paper of mine on this subject, written some years ago. JAS. M'NAB.

Royal Botanic Gardens, Edinburgh.]

Anything that can be suggested for the ornamentation of railway embankments ought not to be lost sight of. It is, perhaps, rather unsafe ground to work upon; still, with due amount of caution, aided by a slight but judicious fencing, difficulties may be overcome. On those slopes where the gradient is not too steep, a great deal could be accomplished. Year by year travelling on our railways continues to increase, while the majority of these travellers, particularly during the summer and autumn months, resort to them for pleasure. The eagerness, therefore, to see all that they possibly can of the surrounding districts, and that, after allowing themselves but a limited time, renders the anxiety to catch a glimpse of everything keener than ordinary.

Trees near Railways.

It is impossible to make all railway banks pleasing to the eye; still much may be done to render them infinitely more attractive than many of them now are, and for this end we think that a reasonable amount of ornamentation may be advisable. As all countries are nearly alike with regard to railway banks, any remarks suggested for one may prove applicable for others. It may be advocated, that to sit and look out of a railway carriage window is a strain upon the eyes, and ought to be avoided as much as possible. This is all very well for those parties constantly travelling on the same line, but, for *bona fide* travellers, whose object is to see all that they possibly can, such advice would scarcely be regarded. Where the strain on the eyes is found to be greatest is when running through forests of trees, where stem after stem seems as if passing in rapid succession, and all perhaps in a continuous line. If the neighbouring proprietors could be induced to thin out such masses of trees, so as to leave them in a sort of waved belt, having Grass between them and the rails, the nearing and distancing would take off that peculiar feeling which is experienced when passing through what has been a forest of Scotch Fir, Larch, or Spruce, growing on level ground. Trees should in no case be near railways; they are apt to be blown down, and fatal consequences might result from such unforeseen and simple causes. Branches also may be blown off, and get into positions capable of doing much mischief. In many parts of the country the proximity of trees to railways cannot be avoided. In numerous districts we see crowds of ill-grown deciduous trees running parallel to the rail, being portions of previous forest land. In such places the removal of all the useless and unshapely trees should be kept in view, leaving only one or two at such distances that no evil could happen, even in the event of their being blown over. A little fresh soil put on the surface of the ground round the roots, after such thinning takes place, would enable those left to take firmer hold of the soil, and thus throw greatly increased vigour into their tops, besides being the means of rendering them more pleasing in the landscape. Few objects are more delightful to the railway traveller than to see the entire outline of a well-furnished tree when so isolated.

Telegraph Posts.

In many districts, and in various parts of the kingdom, great disfigurements are committed on those trees bordering railway banks, caused by the introduction of telegraph wires. Such means of communication must go on; but in many instances it would be far better to cut the trees down altogether than to lop off the branches close to the stems, as is done in some places to a large extent, and that up one side of the trees, in order to prevent their interfering with the telegraph wires, thus rendering many of them absolutely hideous. In some of the northern districts of Scotland, a considerable number of beautiful Birches have been so mutilated, when their entire removal would have been infinitely better, and have been the means of bringing into view distant Birches, whose outline would be more agreeable to look upon, and beyond the chance of interfering with telegraph wires. On nearly every line such mutilations, both on rail and road, are not unfrequent. Telegraph posts themselves, when standing close together, are by no means pleasing objects, passing them as we do in rapid succession. In some districts, such posts stand at much longer distances, and are, therefore, less offensive. The exact result of such distances must now be well ascertained, and if it does turn out that extra strength at greater distances is preferable to smaller posts placed nearer to each other, the greater distances ought in all cases to be adopted, particularly when a renewal of posts has to take place; and, if so arranged, they would prove

infinitely more agreeable for railway travellers. It does seem surprising that with all the ingenuity and forethought displayed in railway matters, telegraph communication should remain much the same as when first constructed, subject as it is to so many accidents, more particularly from the posts being frequently blown over, and also injured from underground decay.

Necessity of Additional Planting to Supply Telegraph Posts, &c.

Judging from the number of these posts annually required, to say nothing of railway sleepers, it is certain that planting is not going on at a sufficient rate in order to meet the increased consumption which must be required by the extension of railways. The Royal Commissioners have done much in this country by encouraging drainage, so as to improve the land for agricultural purposes; they ought also to foster drainage more than hitherto for planting purposes, to enable generations yet to come to be provided with means to meet the constant and increasing demand which must occur both for telegraph posts and railway sleepers. Much comparatively waste land exists throughout the three kingdoms, which, if properly drained, might be turned to good account for planting purposes. If planted with trees suitable for the various soils and situations, they cannot but succeed; and if properly attended to afterwards by judicious thinning and training, keeping in view the different purposes for which they are destined, and each variety being planted on land most suitable for its growth, they cannot fail to become as remunerative to the proprietor as any other crop that could be grown on the land. It is well-known that the progress made by trees planted on land properly prepared for them is much greater than on land where the trees are put in and allowed to take their chance. This is the great point for consideration. Were public money advanced for planting purposes, and properly employed, it would prove quite as advantageous to the lender as the receiver, as similar advances have for drainage purposes. This is a subject perhaps foreign to the object which this paper aims at; still it is worthy of consideration, provided the land to be planted does not approach close to our railways. It must be noted that young trees must not be planted too near a railway, for if so, they will not progress as they ought to do, in consequence of the constant dashing of smoke and steam through them, the injury being greatest on those lines where coal is used instead of coke. While on the subject of a more extended cultivation of trees for railway sleepers, I would particularly call attention to the black Italian Poplar (*Populus monilifera*). This is perhaps the most rapid growing tree we have in cultivation, and will produce in a given number of years more available timber than any other tree yet introduced. Since the commencement of the Larch disease, this Poplar has become very extensively cultivated, and its wood is now used for various agricultural purposes, as well as for railway waggons, &c. The wood of the black Italian Poplar, as well as that produced by some of the other species, all being equally free-growing is worthy of being experimented on for railway-sleepers, so as to ascertain its duration when compared with the ordinary sleepers now in use. If prepared, and laid on broken metal, as sleepers generally are, it may last a very long time. As the black Italian Poplar is always propagated by cuttings, they ought in all cases to be taken from male trees.

Weeds on Railway Slopes.

To return again to our railway banks and slopes. A very large proportion of them are just as they were left by the railway contractor, but since overrun with natural weeds. Some of them have been sown with Grass seeds, but the greatest proportion are covered with Grass, which has found its way into them from various sources, and mostly the Creeping Wheat or Couch Grass (*Triticum repens*). On some steep slopes this Grass may be found very useful for binding the banks, and thus preventing them slipping. It is exceedingly difficult to keep the Couch Grass out of the adjoining hedges, and its running propensities are such that it insinuates itself into the neighbouring pastures and cultivated lands. If the soil should be in the least degree loose, it runs through it with great rapidity. The dried stems of this Grass are exceedingly troublesome while withering on the slopes. It is the cause of many of those autumnal and spring fires which take place on railway banks, being so easily ignited by sparks from railway engines, and, working through the hedges, they also frequently set fire to extensive tracts of wooded land. This is a subject which demands serious attention, as the amount of damage annually sustained from such causes has become very serious, and often leads to unprofitable litigation, resulting, in most cases, in favour of railways, from the plea that such fires may have been occasioned from other incidental causes. Were railway companies enforced to use wire guards over their engine-funnels, as adopted on the American lines, particularly those which have to pass through extensive forest lands, such conflagrations would not be so

frequent; and when fires do occur, these railway companies, where the engine-funnels are protected, ought to have the best of it, particularly when litigation has to be resorted to. It is certainly very annoying to witness extensive tracts along our railway banks covered with black scars, when, at such a trifling expense, wire guards could be procured, and thus prevent many wholesale conflagrations. It would likewise be the means of establishing a more profitable employment of railway slopes. Without such engine guards many of the suggestions for their improvement will be in vain. In almost every district weeds of the most villianous descriptions, both annual and perennial, infest our railway banks, and their seeds are not unfrequently wafted over the neighbouring grounds, to the great annoyance of their proprietors. Roads, walks, lawns, and gardens, also suffer severely from this cause; and unless some means are taken to have them reduced it will soon become, if not already so, a very serious matter for this country. To remedy this growing evil with newly constructed railways, some steps ought to be taken during the first and second years after formation, as any process of cleaning cannot be done afterwards without much trouble and expense. When a railway is first formed, it is generally very easy to tell from what particular cutting on the line the soil has been taken, as the primitive plants on the new made embankments are generally identical with those growing on the banks of the cuttings, although miles apart—thus showing that the soil is full of seeds, and at all depths. On a critical examination of railway slopes all over the country, no plant has turned up, as far as I have been able to ascertain, but what was formerly known to be indigenous to the neighbourhood. When the English railways were first opened, particularly those in the midland counties, the Common Horse Gowan (*Chrysanthemum leucanthemum*) was the most abundant plant along the banks, as large tracts on both sides of the cuttings, and the embankments formed out of them, were perfectly white with its flowers, showing that the seeds had been long buried in the soil. A copious list of indigenous plants may be quoted to show that new-formed railway slopes will produce a large amount of vegetation, both annual and perennial, proving that the soil is abundantly charged with seeds, but identical in all cases, as before stated, with plants found on the surface. To keep railway banks free of weeds, it is absolutely necessary that they should be hoed and raked once or twice before being sown down with permanent Grass or other seeds. By a treatment of this kind a very large amount of noxious weeds would be destroyed while in a germinating state; but if allowed to progress without such means being adopted, the roots will be found to penetrate deep into the ground, and can only be eradicated by a process of trenching. In many districts these weeds are becoming a curse, and will continue to be so unless some means are adopted to turn our railway banks to better account. If railway banks, particularly in those places where the soil, declivity, and exposure is good, be properly cleaned at first, many perennial plants could be introduced, which would prove not only lasting on the medium railway slopes, but could also be turned to good account for feeding and other useful purposes.

Forage Plants.

Many of the perennial leguminous or Pea-tribe plants would prove appropriate for such places, as groups of various kinds are every here and there to be seen on railway banks—not sown, but indigenous to them—all proceeding as if from a common centre, either by the dispersion of seeds or by the running or extension of their roots. Were the seeds of such plants collected and sown, as millions of all can be got if a little care is taken to procure and raise them, they might be afterwards planted on properly cleaned railway embankments. Many of these leguminous plants could be usefully employed for feeding cattle, either in the green or dried state, such as the Crown Vetch (*Coronilla varia*), Sweet Milk Vetch (*Astragalus glycyphyllos*), Kidney Vetch (*Anthyllus vulneraria*), blue-tufted Vetch (*Vicia cracca*), the Bush Vetch (*Vicia sepium*), the Meadow Vetchling (*Lathyrus pratensis*), the Bird's-foot Trefoil (*Lotus corniculatus*), and the Sea-side Pea (*Pisum maritimum*). Besides these, the Medick, Lucerne, Saintfoin, and Melilot, all members of the Pea tribe, would prove useful in such places. This latter group are extensively used on many of the Continental railway slopes, particularly on the Belgian section. Besides leguminous plants, examples in numerous other natural orders may be found equally suitable for growing on railway embankments, also useful for feeding purposes, such as the Burnet (*Poterium sanguisorba*), Comfrey (*Symphytum asperum*), Rib Grass (*Plantago lanceolata*), Queen of the Meadow (*Spiraea ulmaria*), Milfoil or Yarrow (*Achillea Millefolium*), and the copper Day-Lily (*Heemerocallis fulva*). This latter plant has been strongly recommended for cattle-feeding purposes, the leaves being produced earlier in the season than most other kinds. On south exposed railway banks the Day-Lily would

have an imposing appearance, both for its foliage and flowers, as well as the flowers of many of the leguminous and other plants just mentioned. The upright Sea Lyme-grass (*Elymus arenarius*), is a plant which ought to receive more attention than it now does. Although a sea-side plant, it succeeds admirably in gardens, and therefore ought to do well on our railway banks. Its matted running roots prevents the shifting of sand or loose soil, which will render it very useful in some situations. Sir H. Davey proved that this Grass contains more than one third of its weight of sugar, but it is reported not to be eaten by any of our domestic animals owing to the rough texture of its leaves. Surely some use might be made of a plant yielding such a quantity of sugar as the Lyme-grass does, either by cutting and drying in a green state, to be afterwards chopped up for feeding purposes, or for other uses which the agricultural chemist ought to find out. A coarse fabric is said to have been manufactured from the leaves by generations long gone by.

Oil-yielding Plants.

Many plants suitable for the production of oils would be found to succeed well, such as the Peppermint, Spearmint, Lavender, Thyme, and Balm; the Hundred-leaved and Damask Roses could also be grown on many of these banks. The two varieties of Roses just mentioned are extensively cultivated for their essential oils; and now that the use of Rose-water is every day becoming more and more a luxury at the dinner-table, its cultivation on such slopes cannot be too strongly recommended, to say nothing of its beauty and fragrance to the travellers while passing along railways where portions of the slopes are covered with them. The Horse-radish is another plant which may be recommended. It would grow freely, and the extract of its roots might be turned to many good purposes, besides mixing with mustard.

Medicinal Plants.

Why limit ourselves to perennial plants useful for the above-mentioned uses, when numerous plants more immediately connected with the healing art could be profitably grown, such as the Chamomile (*Anthemis nobilis*), Horehound (*Marrubium vulgare*), Rue (*Ruta graveolens*), also the Tansy (*Tanacetum vulgare*), Wormwoods (*Artemisia Abrotanum* and *A. Absinthium*), and the Elecampane (*Inula Helenium*). The Wild Convolvulus (*Convolvulus sepium* and *C. arvensis*) would feel quite at home on all railway banks. A preparation is made from their running roots which is considered highly purgative. Several narcotic plants now extensively used would be found more out of harm's way if grown on railway banks than in garden ground, such as the Henbane (*Hyoscyamus niger*), Belladonna or Deadly Nightshade (*Atropa belladonna*) Monkshood (*Aconitum napellus*), Bittersweet (*Solanum dulcamara*). The Fox-glove (*Digitalis purpurea*) and the Great Mullein (*Verbascum Thapsus*) are also in request by the chemist. Both plants will be found suitable and ornamental for such places. The Chicory (*Cichorium Intybus*), would also succeed admirably: from this plant the chemist and coffee merchant would get abundantly supplied. The Wake-robin (*Arum maculatum*) would also succeed well, and its tubers might be found to yield a superior starch to that produced by the plants grown in woods which is its native habitation.

Fibre-yielding Plants.

It will, perhaps, not be out of place to call attention to the varieties of Yucca or Adam's Needle now in cultivation, as yielding a fibre which ought to be very valuable for paper-making purposes. They are mostly hardy, and all produce a beautiful tough fibre, besides a substance yielded by their stems of the nature of strong gum or glue. The Yuccas are extremely ornamental, both as regards foliage and flowers, and on south-exposed railway banks ought to succeed well. The Yucca gloriosa, which is, perhaps, the hardiest, and the species now most abundant in the country, will be found the most desirable to cultivate. When this plant begins to get into a free growing state it will yield a very large amount of leaves, and will not receive injury by an annual removing of the lower ones; and, for strong fibre purposes, few plants capable of being grown in this country can equal it. It may be remarked, that the Yuccas are rather too valuable as yet to be extensively used for such purposes. If they should be found, after careful experiments, to be serviceable for paper-making or other useful designs, nurserymen might be enabled to turn their attention particularly to it, and would soon be enabled to produce them in quantity. The Yucca, particularly the Y. gloriosa, possesses powers of increasing very different from most other plants yet introduced into this country. It scarcely ever produces seeds, and, if it did, years would elapse before the progeny would become of the least use. To make up for this deficiency, it has had powers of propagation assigned to it very different from most other forms of vegetation. The methods by which the Yucca can be propagated are of two descriptions. If the

roots are carefully bared on one side, which would be sufficient for the plant to endure during one year, a number of egg-shaped bodies, from 4 to 6 inches in circumference, will be found attached to the large fleshy roots, varying in number according to the size of the individual from which they are taken. In some cases as many as fifty have been removed from one plant at a time. During the following year the opposite side may be opened up, and the larger eggs extracted. Many of these egg-shaped bodies, while attached to the plant, will remain long dormant, particularly while the plant is growing with only one stem. If it should happen that the top runs into flower, which takes years to accomplish, or if otherwise injured, no matter from what cause, these egg-shaped bodies will immediately start into growth, and a dense thicket of stems will soon be produced all round the injured one. The same is applicable to some plants where no injury appears. In such a case it will be found that the plant is making an effort to throw up a flowering stem, and, in all likelihood, will do so before the expiry of two years. If these egg-shaped bodies are taken off, as suggested, and placed in soil, keeping the tapered end uppermost, they will very soon push out roots and grow. It is preferable during the first year to keep them under glass; and after being a couple of years in nursery lines, they could be permanently planted out. Another method of propagation is by cutting the flowering stems, or even the stems where the leaves have been taken off, into slices of different thicknesses. After placing them in boxes of light sandy soil, and subjecting them to gentle heat, it will soon be found that numerous shoots will be produced from the sides of each detached portion, as dormant buds exist on the stem, one at the base of every fallen leaf. If it should ever become necessary to remove the tops altogether for fibre purposes, many of the dormant buds along the sides of that part of the stem left will be found to push out numerous shoots, which would never have happened if the top had not been taken off. As more shoots are likely to be produced from the sides of the topped stems than the plant will be able to maintain, all extra ones can be removed, and, if subjected to gentle heat, they will soon produce roots, and make fine plants. It will be seen from the foregoing remarks that this extremely useful plant, now only grown for its Oriental foliage and its magnificent spikes of cream-colored flowers, frequently 8 and 10 feet in height, possesses qualities and means of propagation almost peculiar to itself, if due advantage were taken of it. In several districts of this country tons of the leaves could be procured for experimental purposes; and, if found useful, plenty of gardeners could be induced to turn their attention to its cultivation, so as to enable it to be extensively introduced on our railway banks. I have no hesitation in saying that it will succeed with any ordinary amount of attention. In many districts of Scotland the *Yucca* flowers very freely, and the lower portions of the flowering stems are generally thrown away, instead of being turned to propagating purposes, as above described. The Butcher's Broom (*Ruscus aculeatus*), is another plant which would succeed well on all railway slopes. When properly established, it would cover very large tracts, owing to the peculiar way it produces its suckers. A spade now and then driven down through the roots, so as to separate the rhizomes, will enable the plants to extend themselves more freely. Before being extensively tried, this plant ought first to be experimented on, so as to ascertain its qualities, whether pulp-producing or otherwise. Numerous others might be mentioned, but sufficient has been given to direct the attention of chemists to this most important subject.

Plants for Railway Hedges.

Before leaving the remarks on railway banks and slopes, it may be necessary to say a few words about railway hedges, as this is a subject now well understood and admirably carried out all over the country. In many districts of England they seem to receive much greater attention than many of those planted for the intersectional fencing of land. The plant generally employed for railway fences is the White Thorn, and a useful plant it is for such purposes, and now contracted for as regularly as the rails themselves. On some of the new formed lines the varieties of the evergreen *Hollies* ought to be tried, particularly on those portions of a line running through extensive and well regulated policies in sight of the mansion. In some cases, the proprietors may be induced to pay the extra difference of the plants, while the after-keeping will be much the same as the ordinary Thorn hedge. In all peaty districts the Spruce Fir will make an excellent evergreen fence. It will cover more ground than the Holly; but in mossy situations this extra land will be found of less value. In sandy places, and particularly those near the sea-shore, the Sea Buckthorn (*Hippophaë rhamnoides*) will be found an admirable substitute for Thorns to form hedges. If it should ever be required to make at once an impenetrable live fence, the Hornbeam (*Carpinus Betulus*) will be found the most suitable, and for this purpose clean grown sapling plants,

6 or 7 feet in length, ought to be procured. After the ground has been properly trenched and prepared, the plants should be put in two together, at every 10 or 12 inches, according to the thickness or length of the saplings employed, giving one an inclination to the right and the other to the left. After being trod in firmly, commence to plait all together, taking one set of the plants the one way, and the other set contrary, interlacing them at an angle of 45°. It will be necessary to tie them at top with a piece of wire or rope yarn, and also at several points near the bottom, to keep them in position till they adhere to each other. To facilitate the union, although not absolutely necessary, it will be desirable to take a thin cutting off the bark of several, particularly where they approximate. Shortly afterwards they will grow together, and form an impenetrable net-like fence. From the pressure caused by the plaiting, they will throw out numerous shoots along the stems, which will continue to work in and fill up the interstices. In time the whole length will become an impenetrable mass, all ingrafted together, and will bear cutting-in like any other hedge. Numerous other plants will be found in nursery establishments suitable for such purposes, as the Hazel, Elm, Ash, Beech, Laburnum, &c. Such hedges can be made of any height, depending entirely on the length of the saplings employed. When not in leaf, they will be found extremely ornamental and agreeable to look on, and, therefore, worthy of encouragement, particularly when standing on a level with the rails. If it should ever be wanted to plant such hedges so as to render them useful as well as ornamental, particularly on lands slightly elevated above a damp surface, in such places Willows could be profitably employed, and the annual cuttings taken from them would yield a considerable revenue. Besides, when such plaited hedges are cut for profit, they are more likely to be kept in order than Thorn hedges, particularly when they run through lands which would be profitably employed for the growth of Willows. When planting Willows for such purposes, they could be inserted either as growing plants or cuttings—the latter would be preferable, provided the strip of ground has been properly prepared for them. They should be placed 12 inches apart, and during the first thinning the strongest shoots should be left for plaiting. After the plaiting has been successfully accomplished, all after shoots could be removed for basket-making purposes.

Gardens at Stations.

The only other subject to which I shall allude is that relating to the further ornamentation of the land in the immediate vicinity of railway stations. This is a most important point, and one which ought to be more generally attended to, and, if persevered in, will amply compensate for any of those eyesores previously complained of. Of late years a very great improvement has been effected on them, and we are glad to observe that the taste for station embellishment is greatly on the increase, as we now see one railway vieing with another for this laudable end. Almost all the extra decoration is due to the horticultural taste of the station-master or those under him. We do not quite agree with all the freaks exhibited on roadside stations; still such freaks in the meantime ought not to be objected to, as they often lead to other and better suggestions. When we consider the great diversity in the tastes and ideas of those for whose gratification they are chiefly intended, allowance must be made by the public for the primitive notions which are displayed at some of them. The great diversity in localities and soils where intermediate stations have to be placed, must in many instances call forth a great amount of ingenuity from those in charge, so as to turn them to the best account. It will be invidious in the meantime to enter upon their merits, notwithstanding that very good taste has been devoted to many of them. As this is a wide subject, it ought, some time or other, to be taken up in detail, so as to give credit to those to whom credit is due, and to point out to others what is capable of being done. In the meantime, we shall content ourselves by urging as much as possible a continued increase in station embellishments. It is to be hoped that railway directors will encourage it as much as possible. In all new-formed stations those interested would do well to examine as many as they can, and select the good points of each. Some of the stations are, perhaps, too much hampered for room, and in some we find a wall of rock rising almost perpendicularly on each side. Such stations have charms unseen, and, in the hands of a skilful garden architect, could be made to assume forms at once interesting and characteristic of the district. Such schemes would take years to accomplish, as stones are always in demand, no matter of what kind, their gradual removal would always be facilitating the end in view. Many of these stations, where the rocks are not excessively high, could have the material removed down to the surface level for 70, 80, or 100 feet in breadth, till the time arrives for their final arrangement. Instead of upright rocky walls, having a narrow platform and the rails between, where the sun rarely penetrates, we ought to see sloping rocky banks,

made as irregular as it is possible to work them. The hollow places formed could be filled with soil, to be planted with Coniferae or shrubs and flowers suitable for rocky places. It is greatly to be desired that civil engineers will consider all these hints while designing new station buildings. In the station building department a very great improvement has of late been effected, but much still remains to be done. Any one travelling over the kingdom cannot fail to observe the comfortable-looking stations on many of the English lines where brick and white stone are employed, and surrounded by well-kept Grass and shrubs. If a little more ground could be allowed round some of the Scottish stations, they would soon be able to vie with the English in every respect. When the train comes to a standstill, it is certainly pleasant to cast the eyes on these delightful spots, particularly after a weary run of many miles, and then rest contented till arriving at another station. By a continued improvement of the kind suggested, delicate eyes may be kept at rest, instead of straining them on tree stems and telegraph posts, knowing that something more pleasing is in store for them at the next stopping place.

General Observations.

Numerous other plants might be mentioned, both useful and economical; but sufficient have been given to show what will do if properly tried. Parties leasing portions of railway banks would soon find out many paying perennial crops. None but perennial crops should ever be introduced; if otherwise, they would become extensively used for culinary vegetables, which would necessitate an annual digging and manuring, and thus cause a wasting and wearing down of the banks, which would not be the case with perennial crops. Strawberries have been frequently recommended, but never carried out. If to be extensively grown, they should be planted in diagonal lines, as all perennial plants ought to be on such places. Of the different plants here proposed for growing on railway embankments, those which yield fibre are the kinds which ought to receive the greatest amount of attention, particularly those suitable for the making of paper, or producing pulp which can be used in various branches of the arts. The demand for paper making materials has now grown to such an extent that foreign countries may have a difficulty in continuing to keep up a supply. Many experiments have at various times been made with plants for this desirable end; and it is well known that numerous are the kinds which, if due attention is paid to them, will yield pulp suitable for such purposes. The expense of raising them on soil capable of ordinary cultivation makes such home materials rather expensive to obtain; but if such plants can be grown on railway slopes, it is but natural to suppose that the cost of producing a suitable material on such places ought to be greatly diminished. In order that this subject should receive that attention which it deservedly requires, the Society of Arts or other public influential bodies, ought to offer a medal or other award for experiments on pulp-producing plants capable of being reared on railway embankments, and thus be the medium of benefiting the country by rendering such neglected places serviceable for the public good, the demand for paper being annually on the increase, and likely to be so for generations to come.

Poison of Nettles.—M. Naudin maintains that after a violent storm of wind the sting of the Nettle is deprived of its virulence.

THE GARDEN IN THE HOUSE.

WINDOW GARDENS.

Our object is not to instruct those who have gardeners and green-houses, but to merely give a few hints to such as have but little time and convenience for such work, and yet love flowers with a devotion unsurpassed by those more favourably situated for its gratification. Plants, like ourselves, need air, light, warmth, food, and water, and they must have all these in sufficient quantities, or they will suffer and die. Abundance of the best of food for plants in pots is found in old meadows, where Grass has grown a long time. A pile of turf laid up to rot makes excellent potting earth. We can give no rule for watering. Keep the earth moist, just about as you observe it in the garden in what we call a "growing time," that is, a few hours after a brisk thunder shower. Most of our plants are injured by too much heat. For a general collection of house plants it is not well to allow the thermometer to be above 70°, and if they could be kept in a room where the thermometer would usually not range above 65°, it would be the better. In the night time 50° is high enough. Give a little fresh air every fine day, and all the sun-light attainable. Cleanliness is as necessary to plants as to anything else; therefore secure them from dust, if possible. Sweeping carpets is almost enough to kill both plants and sweepers. It will be a happy day for our lungs, as well as for the lungs of plants, when we get a good substitute for carpets, something that will not raise a cloud of dust every time a step is taken. Until

this good time comes, give the whole plant a good syringing occasionally, or a bath in a pail of water. A little moisture in the air of a room is pleasant and healthy. We would not say that a green-house or a Mushroom-house would be a good place to live in, but we do say that a room that will keep a few plants in good health, other things being favourable, will keep a family in the same desirable condition. The family can breathe the confined, dusty, dry, over-

heated air of a room and live, because they are out in the fresh air a good portion of the time, but those who are confined to the air of our living rooms the greatest number of hours are the most delicate, and the plants having to remain in these over-heated, ill-ventilated, and dusty rooms, without a moment's relief, must droop and die. Cleanliness, fresh air, moderate heat, and a moist atmosphere will secure healthy plants. Where a bay window is devoted to plants, glass doors should be placed between them and the living room, as a partial protection from dust. These can be closed a part of the day, and thus a lower temperature be obtained for the plants than would be comfortable for the occupants. A library or spare room that is not constantly used is an excellent place for plants, because such a room is kept rather cool most of the time. Plants suitable for winter flowering indoors are numerous, but none afford so much pleasure as a good collection of bulbs, such as Hyacinths, Tulips, Narcissus, and others. In the garden there are usually a few plants that may be taken up and potted. The

Ivy, Madeira Vine, and Cobæa scandens are graceful climbers, and will bear almost any amount of bad treatment. Tuberoses that have not bloomed in the garden and are showing flower-stems may be taken up and potted, and will flower in early winter. A root of the Dicentra will also give satisfaction. A pot of Mignonette costs but a few pence, and not many expensive plants will afford as much pleasure. Sow the seeds in August of plants to bloom at Christmas. The Sweet Alyssum treated as

Window Garden with Glass Doors.

Open Bay Window Garden.

advised for Mignonette will also please, and nothing will make up better in button-hole bouquets than these sweet little flowers. A few larger plants are desirable, and the Calla, Dracæna, and Begonia are very patient under almost any kind of treatment. We have not, however, space to enlarge on this subject, but will merely say that a few Lilies, like longiflorum, auratum, and lancifolium, though not often seen in the house, will afford a pleasant surprise, and flower in the order named.—*Tick's Floral Guide*.

PLANT STANDS FOR HALLS.

In outer halls stands of growing plants form very effective ornaments, but the plants selected for this purpose should be such as would not feel the effects of cold currents of air; for, during the winter months in an outer hall, they would, of course, be subject to sudden changes of temperature; while, during the summer, almost any plant may be placed under such circumstances with the greatest safety. The size of plants used for this purpose must bear some kind of proportion to the size of the hall in which they are placed, and as to the shape and the material of which the stands are made, that must depend on the taste of the purchaser; but the dearest and most ornamental, when fitted up, often do not look so well as those of a less decorative character. The plant selected for the centre should always be the tallest, a Dracæna, Cocoa-nut Palm, or India-rubber plant, being best adapted for this purpose. Round this should be grouped other plants either remarkable for flowers or foliage, which will be set off to advantage by that selected for the centre. Round the edge should be placed something of a drooping character, which will hang down gracefully and produce a good effect. For a stand in a hall, which is not heated in any way, there are no plants better suited than hardy British Ferns, which withstand cold draughts well, and preserve their foliage fresh and green all the year round. For town houses nothing is so suitable as Ferns, as they grow well where other plants would droop and fade in a few days. A handsome stand of British Ferns could be arranged as follows:—In the centre should be set a tall plant of *Lastrea Felix-mas*; then, grouped round it, a few plants of *Scelopendrium vulgare*, and again, outside of these, such varieties as *Asplenium adiantum-nigrum*, *A. marinum*, *A. Trichomanes*, *Blechnum Spicant*, and *Polypodium vulgare*. The Parsley Fern (*Allosorus crispus*), too, should not be forgotten. Ferns succeed best when each is set in a separate pot, and, when planting them in this way, care should be taken not to crush any of the fronds, as, if bruised, they fade at once. The size of the pots should be regulated by the stand in which they are to be placed; if a large one is employed, the pot in which the centre Fern is to be planted should be a 24-sized one; for those outside of it 48-sized pots will be large enough; and for those round the outer edge 60-sized ones will suffice. In the bottom of each pot should be placed some broken crocks, for drainage—not, as is too often the case, thrown in in any way, but placed so that the moisture will drain down through them, without the soil choking them up. Over the crocks a little Cocoa-nut fibre, or Moss, should be placed, and over that, again, a little of the soil in which the plants are to be potted. If Ferns, they should be planted in a mixture of leaf mould, rotten turf, and peat, a good dash of silver-sand being thrown in to keep the whole porous. On the surface of the pots, and between them, should be put wood Moss, as in the case of stands for sitting-rooms. A common seed-pan filled with *Selaginella denticulata* dropped into a small vase has a fine appearance; long sprays grow out over the sides of the vase, and droop down 8 or 10 inches, producing a charming effect. During the summer time a few Roses, or similar flowers, might be placed, if desired, amongst the *Selaginella*. A. HASSARD.

Floral Funerals.—Floral funerals are more frequent than is generally supposed. Only the other day one of our country papers contained an account of the funeral of the wife of the son of Sir Charles Locock, Bart. The outer coffin was polished, and, instead of being covered with the pall, it was covered with costly flowers, and festoons of flowers were entwined around it. The mourners also each carried a bouquet of white flowers, and were not apparelled in the usual habiliments of mourning. A muffled peal was rung both before and after the interment, and also as the body was being borne from the church to the grave, and after the coffin had been lowered into its last resting-place the mourners threw their bouquets upon it, so that nothing was visible but a mass of flowers. Some twenty years ago, when Dahlia-shows were frequent among the operative weavers of Spitalfields and Bethnal Green, a well-known Dahlia-grower was followed to the grave by a number of weavers, who carried bouquets of his favourite flowers in their hands, the coffin being covered with an immense number of the same flowers.

THE ARBORETUM.

DIRECTIONS AS TO PLANTING.

1. First, see that the roots of the tree or shrub which you are about to plant are in proper condition. It should be provided with a sufficiency of small fibrous roots, for it is from the spongioles at the extremities of these that the plant derives its nourishment. Trees vary in the form of their roots, from the dense mass of tangled fibres close to the crown, which makes the *Rhododendron* so safe to transplant, to the long, coarse, thick tap-root, which renders transplantation a dangerous process with some trees unless removed young. But these tap-roots emit from various parts tufts of fibres, and it is on these being uninjured, and in sufficient quantity, that the success of the planting will depend.

2. It is evident, then, that, should it be found necessary to prune the root, the knife should be applied to the big coarse taps, but not to the fine hair-like rootlets, all of which should be carefully preserved.

3. Let the hole dug to receive the plant be rather larger than required by the roots when spread out.

4. If possible, dig the holes which are to receive the plant some days or weeks before the planting takes place, so as to leave the interior of the hole exposed meanwhile to the fertilising influences of the atmosphere, rain, &c.

5. Rainy, or at least damp, cloudy weather, is by far the best time for planting. Avoid as much as possible planting during sunshine, or frost, or a run of dry weather.

6. If, for any reason, you are unable to plant your trees and shrubs for some time after receiving them from the nurseries, keep them meanwhile in some cool, dark shed, with wet Moss or matting flung over the roots. These must be carefully guarded from three enemies, viz., frost, drought, and light. Sunshine is death to roots.

7. In planting, see that the fibrous roots are not cramped or tangled in a mass, but spread them out carefully, so that they occupy nearly the same position as they did before the plant was taken up.

8. If the tree has been reared in a pot, the roots will most likely be found coiled up spirally into a dense mass. If so, they must, before planting, be patiently unravelled, and the fragments of pottery placed for drainage extricated. In doing so, care must be taken not to injure the extremities of the rootlets, which must be placed as deftly as possible in the hole, and spread out in such positions as that, when they grow, they shall not resume the twisted form.

9. Beware of planting too deep. The tree should not be fixed in the ground lower than will bring the soil, when the hole is filled, an inch or two above the collar of the tree. The collar is the spot where the ascending axis (the stem) meets the descending axis (the root). Thousands of young trees perish annually from being planted too deep. In situations exposed to violent winds it may be allowable to plant a little deeper; but it is only meeting one evil by substituting another, and it would be preferable to undergo the expense and trouble of staking the young trees where it is required.

10. When the plant is placed in the hole, and the roots well spread into their natural position, fill the hole half full with some fine soil, different, if possible, from that in which the hole has been dug. Then shake this soil into the interstices between the roots, by gently pulling the stem up and down just enough for the purpose, and afterwards tread the soil lightly in. You may then proceed to fill up the hole, and, when done, again tread the soil in pretty firmly before making the surface neat.

11. See that the stem, when planted, be quite perpendicular. If the tree is of that shape or size as that the wind may sway it about, and thus disturb the roots, it should be fixed to a firm stake till it has become settled. See that the stake is so attached that it shall not, by its contact, fray or wound the bark of the tree.

12. If the soil be very dry at the time of planting, mulching must be resorted to. That means watering abundantly, and in relays as the first watering gets absorbed, so as to make sure of saturating with water all the ground about the roots. Mere surface watering is a sham. You must water abundantly and repeatedly, till no doubt remains as to the water (which percolates very slowly through dry dusty soil) having reached the lowest roots. Anything short of that is useless.

13. Avoid planting on raised soil or mounds, unless in very exceptional cases, such as low, damp, swampy spots. Unless in very wet seasons, very little of the fertilising rain reaches the roots of trees planted on mounds, as the sloping sides of the mound carry the water, as it falls, away from the roots of the tree to be wasted in the surrounding ground. Plants thus deprived of their fair share of moisture never thrive well, and, in dry summers, often die. If you take up a tree thus circumstanced, you will find the ground about its roots quite dry and parched.

14. On the contrary, it is a good practice to scoop a kind of

shallow basin round young newly-planted trees, by slightly elevating the soil at a little distance round the stem, thus inclining it inwards towards the plant. In this way the rain, as it falls, is directed towards, instead of being conducted away from, the roots.

15. In planting raised banks for hedges or screens, bear in mind the above, and let the top of the ridge, on which the plants are set, be hollowed a little, so as to incline the water-shed towards the roots.

16. When a tree is planted on a lawn, or any other grassy site, do not let the herbage come close up to its stem, but cut away a circle of the turf of larger or smaller diameter, according to the size of the tree. As a rule (of course with exceptions), the roots of a tree extend as far as the extremities of its horizontal branches, and that should be (until a tree has grown large) the measure of the circle that is to be bared of turf and left open to the beneficial influences of the air, rain, and sun.

17. With trees planted in unfurfed soil, similar care is to be taken not to allow rank and tall weeds to grow within a certain radius of the stem. Many a young plantation has been ruined by the encroachment of luxuriant weeds, which monopolise the nutriment of the soil, prevent the access of rain and sunlight, and choke the foliage of the lower branches of the trees.

18. As a rule trees, especially Conifers, dislike coarse manure about their roots. But decayed turves, rotten leaf mould, and, indeed, any mixed refuse or rubbish, especially if of a different nature from the soil in which the plantation is made, form composts which wonderfully stimulate the growth of newly-planted trees.

19. If a plantation be made in stony soil do not remove the stones. To many trees they are rather beneficial than otherwise, and to very few do they seem detrimental. Experiment has proved that the removal of stones from stony land impairs its fertility to a remarkable degree, at least for some years.

20. In the purchase of grafted or budded trees see that the union between the graft or bud and the stock be properly effected. Sometimes (and this chiefly occurs amongst Continental growers) a slim graft is embedded on a thick bludgeon of a stock out of all proportion to it. Sometimes it is a vigorously-shooting species that is wedded to a slow-growing stock which cannot furnish the quantity of sap required. In both cases failure sooner or later is the result. In budded plants it is the stock that is generally the most delicate part. Unless it is healthy and well-stored with sap, the bud, however vigorous at first, will gradually decay.

21. For choice and delicate trees and shrubs, and generally for such as are liable to injury from the cold of our climate, do not select the lowest and most sheltered spots to plant them in. In valleys and enclosures they suffer more from frosts than in more elevated and open situations. The protection required by plants that are impressible to our climatic conditions is rather the screening them from the bitterness of our north-east winds in spring than the shutting them out from healthy summer breezes. In closely-secluded nooks and dales such plants are stimulated into early growth in spring and late growth in autumn, and, in both cases, the tender sappy shoots are unable to resist frost. In more open and exposed situations the growth is shorter, but the wood of the shoots is better ripened.

22. In peaty soils there generally exists between the surface-peat and the sub-soil (whether sand or gravel), a stratum, from 1 to 6 inches thick, of a hard gritty substance, impermeable to water, which is locally denominated "rust" or "pan." Until this "rust" or "pan" be quite broken through by the process of trenching (for which a pick-axe is generally indispensable), it is in vain to plant in such soil, as it will nourish nothing but the indigenous Heaths and Scotch Fir. But once trenched and the "rust" broken through, the land becomes very fertile, and peculiarly well adapted to the growth of trees and shrubs of all kinds.

23. Plants reared in peaty or similar light soils bear transplantation better than those grown in heavy lands. The reason is, that in light and porous soils, the roots are mostly globed into fibrous tufts near the stem, whereas in strong land the roots of plants wander farther away in search of moisture, &c., and through a denser medium, so that they become elongated and coarse. All tap-rooted plants, whether the tap-root be congenital or superinduced by the nature of the soil, should be transplanted while young, otherwise they have little chance of surviving the process. Hence it is, that young plants growing spontaneously in woods, whether self-sown young trees or suckers sent up by older ones, and, generally saplings undisciplined by nursery cultivation, scarcely ever survive transplantation. Plants with fibrous roots are generally taken up with "balls" that is, with more or less of soil clinging to the dense trusses of roots, and in that state, transplantation is a safe and easy process. Of this, Rhododendrons afford a striking instance, as, when taken up with good "balls," they can be moved with impunity at almost any season of the year.

24. Trees and shrubs intended for transplantation should not

be left more than two years without being moved, or (which in most cases is equivalent) "spaded." This last process consists in passing a spade (or other tool peculiarly constructed for the purpose) round and under the tree, so as to cut off the tap-root (if any) and to confine the lateral roots within a certain given space. This work should be done in the early autumn, so that there may be time for fresh rootlets to be pushed forth inside the ball, to replace those which were cut off outside of it. A plant so treated will hardly ever fail of successful transplantation, as it is isolated from the surrounding soil, and when transplanted, will extend its roots in its new locality without sensibly feeling the difference.

25. The safe removal of large trees is ensured by a process identical in principle with the above, but on a proportionately larger scale. A trench is dug round the tree, one season before its intended removal, at such a distance from the main trunk as may be considered sufficient to leave roots enough attached to the tree to feed it when removed to its new position. This trench cuts off all the roots extending beyond its inner circumference. The spade, or other special tool, is then pushed successively from all parts of the trench as far under the roots of the tree as possible, so as to intersect the "tap," if any. The trench is then filled in, and the tree proceeds, during that season, to develop fresh rootlets within and around the "ball" left inside of the trench. By the ensuing season this ball will contain within itself all the roots necessary to the life and growth of the plant. Then, by proper machinery of a simple nature, both the tree and its ball of roots, with plenty of soil adhering to them, can be lifted up and safely removed to the new site which the tree is intended to occupy.

26. Transplanting may be performed at any time from October to April, according to the nature of the season. But the universal canon to be observed is to plant as much as possible during wet or cloudy weather, and to refrain in sunshine, drought, or frost. Such intervals of forced inaction may be profitably employed in settling the spot where each tree is to be placed, in digging the holes, and in providing the compost to be put round the roots when the planting is performed.

27. The sooner after the receipt of the trees from the nurseries they are finally planted, the better; but if there must be some delay in planting them, it is better to keep them in a dark shed, as before directed, than to "lay them in by the heels," as placing them hurriedly and temporarily into the ground is technically called.

28. In moving trees of any size, it is advantageous to place them, when re-planted, in the same position, with respect to the cardinal points, as they occupied before being moved. In other words, it is best that the same side of the trees should face the west (for instance) as faced the west before removal.

29. Do not unduly cut up your grassy expanses by dotting too many single specimens, or, worse still, too many flower beds, or small clumps over its surface. What single specimens you do plant should be of the very finest or rarest species. If Conifers, they should feather to the ground; if deciduous trees, they should be of such species as that when the branches are allowed to ramify 5 to 6 feet high on the trunk, they should dip to the ground, as in the Tulip tree, Catalpa, Horse Chestnut, and many other trees. Amongst them may also be interspersed a few pendulous trees, which, when not too numerous, add a peculiar grace to the scene.—*Heatherside Manual*.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

The Prostrate Cherry (*Cerasus depressa*).—A specimen of this at Heatherside has a trunk 1 foot high, nearly a foot in diameter, the branches hugging the ground and covering a space of many yards. It is one of the most singular objects we have ever seen, and would prove a most effective shrub for many positions in the garden.—A. MONGRETTEN.

Catalpa for Posts.—The fact that Catalpa wood almost, if not quite, equals Locust for durability when set for posts has long been known. It is one of our most ornamental trees both for bloom and for foliage; and on account of its rapid growth is a favourite in lawns and along avenues. The annual rings seen when the stem is sawed across are often one inch in thickness, and this gives the wood great beauty when worked for furniture or put to other like uses.

Beech as a Hedge Plant.—About Marchmont, Beech hedges line the public roads for miles, and are quite an ornament to the country. There is no doubt that Beech is about the very best plant for hedges, and that it forms a better protection to animals than Thorn. In planting a Beech hedge, a standard Thorn planted at certain distances apart would produce a good effect, especially if trimmed a little with the shears once a year, to keep the heads in shape, but not, of course, to such an extent as to spoil the flowering in spring.—H. K.

The Great "Forest Tree" of Moray.—A magnificent aboriginal Pine (*Pinus sylvestris*) is, *par excellence*, known by the name of the "Forest Tree" to the frequenters of the forest of Donaway, which for miles surrounds the castle of the same name, the northern residence of the Earls of Moray. The "Forest Tree" is 15 feet in circumference, and rises to the height of 50 feet from the ground without a branch, and terminating in a vast spreading head, like a gigantic green tent, impervious to snow or rain. In summer its topmost boughs are covered with the blossoms of the white wild Rose, which has climbed to the summit of this mighty tree.—C. E. STUART.

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

Indoor Fruit Department.

Begin to collect leaves and stable litter for forming a fermenting bed on the inside border of the early Vinery. This will be needed about the beginning of next month; mix the materials well together and let them remain in any spare corner until required. If a Vinery is to be started about the new year, it should now be pruned and cleaned. Give the inside borders a liberal rich top-dressing, and keep the Vines quite cool by withholding fire-heat and admitting plenty of air. Painting the rods is not so much practised now as it was at one time; here, no Vines were ever painted with any kind of mixture, there being no insect pests to eradicate. All loose bark is scrapped off, but not into the quick; and a good scrubbing is afterwards given with a hard brush and soft soapy water. This is quite sufficient. Where red spider has, however, been troublesome throughout the summer, some stronger means may be desirable. In that case, painting may be resorted to with advantage; the paint should consist of equal quantities of sulphur, soot, lime, and clay, dissolved and thoroughly incorporated together; after scraping and washing the rods, carefully paint them with this mixture; do it with a hard hair-brush, inserting it well into the crevices about the spurs, and leaving only the eye or bud untouched; also wash the walls with dissolved hot lime. Mealy bug is the most troublesome pest to get clear of when once established in a Vinery, and to clear it out thoroughly the means just named must be vigorously applied. In pruning, if a few eyes are wanted for purposes of propagation in the spring, they must be selected now; choose the most prominent buds on the best ripened wood, that is wood that is hardest and has the smallest pith. Tie the prunings of each variety carefully up together, and place them in any outside border with a little soil about their base, where, with a mat thrown over them during severe frost, they may remain until wanted in the spring. Do not cast away the smallest of the young Vines which have been grown this summer if a few fruiting pot canes are wanted for forcing early next autumn. These small Vines, though they may be too weak for planting, are very suitable for cutting over to within a couple of eyes from the bottom, and starting early, to be well ripened for early fruiting. Such Vines are termed "cut backs," and they ripen their wood sooner than those started from eyes the same season; but, except for very early work, nothing surpasses a one-year old Vine; and "cut backs" should never be used for planting out in a border, as their roots, after being confined two years in pots, get badly entangled. Look diligently after decaying berries in hanging bunches; do not get into a system or periodical round of looking over them once a week; on the contrary, always remove such berries as soon as visible. The surface of inside borders should now be very dry, avoid, therefore, disturbing it in any way, as dust arising therefrom settles on the fruit. Every favourable opportunity should be taken to give Pine plants a little fresh air, as the time is approaching when the ventilators of Pineries will rarely be opened, and the hardier the plants are grown now the less will they suffer during confinement. Late potted suckers will now be pretty well rooted; examine the soil in which they are grown, and see that it does not get over dry. Sufficient water should just be given to maintain the roots in a healthy condition. Ripe fruits should all be supported by means of stakes inserted in the pots. By fastening the base of the crown to the stakes, the fruit is prevented from falling, either to one side or the other, and the crowns are kept from getting twisted, as they often are when not thus supported.—J. MUIR, *Clontarf*.

Hardy Fruits.

Peaches, Nectarines, and Apricots can only be properly classed in our climate as half-hardy fruits, and hence their treatment should often be widely different from that of really hardy fruits, such as Cherries and Apples. Even many Pears can hardly be said to have their blossoms hardy in our climate, and, therefore, the practice of early autumnal pruning, nailing, and training of the trees, as I have lately directed for Cherries is hardly to be recommended. On the contrary, summer and spring pruning are safest for them. The later the pruning the later also the flowering; and the later the flowering the greater the certainty of a crop. The long spurs left from summer stoppings prove outlets for the first flush of the sap. They are not only the first served, and the first to break into leaf, but, in doing so, they take the pressure, as it were, off the first buds, enabling them to rest in safety perhaps a week or a fortnight longer; and, in thus resting, a crop is secured. In pursuit of a late growth, and bud opening in the spring, it is good and safe practice to unnaïl Peaches, Nectarines, and Apricots at this season, and draw the bulk of the tree away from the wall.

The operation, however, must be performed with care; sufficient leaders must be left to support the trees and prevent them from breaking. This object ensured, the trees can hardly be too much loosened nor too far tied back from the walls. The latter are the sources of heat, while now, and for the next four months, the trees require for the safety of their crops, not heat, but cold. Besides, the temperature is much more uniform 6 inches or a foot from the wall, than on it; a short period of winter sunshine runs up the temperature on the face of the wall to summer-heat; the night comes and cools it down to the level of the surrounding atmosphere, and the trees are thus, day by day, exposed to the utmost extremes of temperature. If we preserve the sap of the trees at rest throughout the dead season, we not only do our heat to ensure a crop, but to reserve the vital forces, and keep intact the health of the trees. Some add increased force to the retarding influence of unnaïling by shading the trees with a loose thatching of dry Fern fronds or straw. Such non-conducting shades moderate the extremes alike of heat and cold, and are of more service in winter in resisting the insinuating influences of gleams of sunshine than in resisting the force of extreme cold. In cases where such expedients are thought desirable they ought not to be employed till all the leaves have fallen, as the unnaïling and shading ought not, in any case, to be performed simultaneously, as the wood is benefited by having its wall side exposed for a few weeks to light and air. As remarked in former calendars, October Peaches are abnormally late this season; and, if not yet ripe, they should be at once enclosed with glass lights. The Salway and Lord Palmerston have been exceptionally fine this autumn, as well as unusually late. The general run of mild weather has developed their size to the utmost, and their flavour has proved all that could be desired. The nights, however, are becoming frosty; and glass, to finish those still unripe, has therefore become necessary.—D. T. FISH.

Indoor Plant Department.

In conservatories, forced Camellias should now be coming nicely into bloom. Tall Chrysanthemums planted here and there amongst them have a fine effect. The earliest lot of the latter, both of tall and dwarf kinds, should be now in bloom; a second portion should be put in an intermediate temperature, to bring them on a little, and the main part left in as cool a house as possible. In many cases Chrysanthemums have not yet been taken indoors; but it is not considered advisable to keep them out longer, as there is danger of frost injuring the buds. Some of the old plants planted out in borders, and well furnished with flower buds, should be lifted and potted for indoor decoration. Bouvardias may be neatly but sparingly staked and brought into the conservatory as they come into flower. Such Cyclamens as are in frames should be syringed overhead every dry day, plenty of air given them, and, at the same time, a little fire heat. Herbaceous Calceolarias and Cinerarias should be re-potted when required, and kept in cool airy pits near the glass. Lantanas that were well cut back in August should be beautifully in bloom, and taken from the forcing pit to the conservatory. Salvias of various kinds lately cut back should also be coming in nicely. Early potted Hyacinths, Tulips, and Narcissi that have filled their pots with roots, and the leaves of which have commenced to push, should be taken from positions where they have been plunged and placed in an intermediate temperature on the house floor. After a few days their tops will be better able to withstand light, when the pots should be plunged in a very gentle bottom-heat near the glass. Mignonette in 6-inch pots should be thinned out to a few plants; it is generally sown in the pots in which it blooms, for it does not transplant well. Should a larger pot be required, the plants should be shifted wholly without breaking the balls. Heaths and Epacris should be arranged in airy positions in the greenhouse near the glass. Epacris should be neatly tied to light supports, as should also Azaleas, Chorozemas, Genetyllis, and other plants of that kind. The chief operations in stoves will consist in washing leaves, staking and arranging, so as to give all plants an equal amount of light. Amongst flowering plants Ixoras will be still in fine condition; indeed they may be regarded as perpetual bloomers. Aphelandra Roeziana will also now be beautifully in bloom. Among fine-foliaged plants, one of the most conspicuous is the variegated Pine-apple, which, when grown near the glass, assumes a reddish hue. Forcing pits, should be full of Dutch bulbs, Chrysanthemums, and hardy shrubs, such as Lilacs, Deutzias, Azaleas, Rhododendrons, Daphne Mezereum, Kalmias, and others. Azaleas that have been gradually inured to early forcing should be used for the earliest work. A temperature of 55° at night and 65° by day, and a position near the glass, in a light house, suits them admirably. Too much heat is a great evil in Azalea forcing. In order to hasten a change of colour in Aucuba berries, they should be placed in a gentle heat. Good crowns of Lily of the Valley should now be lifted and potted. When potted, place them on shelves arranged one above the other in a warm moist house. On

these shelves the pots should be arranged quite close to each other, Cocoa-nut fibre, being worked in between them, and a layer of 2 inches or so of it placed over them. They may remain in this position until they throw up leaves, when they should be removed to a lighter situation. If required for cut blooms only, they simply should be put into boxes in a compost of leaf-mould, loam, and a little thoroughly decayed manure and sand. Poinsettias should be plunged in bottom-heat, in order to cause them to produce larger flowers and bracts. Old plants that have been placed out of doors or in cool houses during the summer months should also be similarly treated; but those required for late work should not be plunged. *Thysanacanthus rutilans*, *Justicia*, young plants of *Pentas carnea*, plants of *Eucharis amazonica* lately rested, *Heliotropes* from summer cuttings, *Tradescantias*, such as *Warszewiczii*, *discolor*, &c., and many other plants, should now be plunged in bottom-heat.—F.

The Flower Garden and Pleasure Grounds.

The weather, being still comparatively mild, beds of *Pelargoniums*, *Calceolarias*, and *Verbenas* are still in considerable beauty; and, where it is not intended to preserve such plants, they may be allowed to retain their position in the beds as long as they remain attractive. Some of the winter and spring-flowering bedding plants, such as *Aubrietias* and the *Forget-me-nots*, which are already showing flower, will be in proper condition to take the place of the summer bedders as soon as the latter are removed. The two systems, *i.e.*, spring and summer bedding, may, therefore, thus be made to unite with each other, and in that way prevent the flower garden ever being entirely devoid of flowering plants. All bedding plants intended to be preserved should now be in a place of safety, and will, together with rooted and partially-rooted cuttings, require to be frequently attended to in the way of removing all decaying leaves. Water should be given sparingly at present, as about this time damp is more to be dreaded than frost. A glass roof will, probably, for some time to come, be sufficient protection against frost; and an occasional brisk fire during fine days, when abundance of air can be given freely at the same time, will be found to be beneficial in warding off damp. Most of the many varieties of *Fuchsias* form very ornamental and permanent flower-beds, more particularly the white corolla'd varieties of the *Madame Cornelliussen* type. When planted out in the open air they may generally be treated as ordinary hardy herbaceous plants; or, during very severe winters, the surface of the beds containing them may be mulched with a slight covering of cinder ashes, old tan, or sawdust. The *Cineraria maritima* is also an exceedingly useful hardy bedding plant; as a white or silver-foliaged marginal plant, it is, perhaps, unsurpassed, and will last for any number of years; indeed, the older the plants the more white the foliage becomes. It requires no protection during ordinary winters, but should not be cut down until about the beginning of May, when it will be found to be breaking close to the surface of the soil; after being cut close down it will immediately break into growth and become at once effective. It is of the greatest value in ribbon bordering, contrasting, as it does, agreeably with the *Perilla*, or, better still, with *Dell's* dark-leaved bedding Beet. For this purpose it is generally to be preferred, as a silver-leaved plant, to the *Centaurea*, as it can be cut or pinched in with impunity. Continue to gather seeds of ornamental trees, shrubs, herbaceous plants, and annual flowers, as they become ripe. Chestnuts, Walnuts, and Acorns, may be sown at once; while smaller seeds, and those likely to be injured while germinating by spring frosts, need not be sown before the beginning of March.—P. GRIEVE, *Uxford, Bury St. Edmunds*.

Hardy Flowers, Alpine Plants, and the Wild Garden.

So essential is it in a calendar of operations that the operator should possess a fair knowledge of the materials upon which he has to operate, that I do not hesitate once again to pass in review those plants, which, though gradually decreasing in number, yet contribute a fair amount of floral beauty to the several departments which come under the above heading. To the large and well defined natural order *Compositæ*—certainly the richest in numbers—belong our *Chrysanthemums*, invaluable for winter work; but, as yet, they are only developing their buds, and, in truth, they scarcely belong to my department. Those starry flowers, *Michaelmas Daisies*, are radiantly expressing their silent thanks for bright blinks of autumn sunshine. To the species of the genus *Aster*, the term "legion" is most appropriate; they vary in height from 2 to 3 inches, as represented by the *Alpine* forms, such as *A. alpinus*, *ramosus*, and *altaicus* (all summer bloomers), to the giant American types of New England origin, as the name *Novæ Angliæ* implies, which attain a height of 6 and even 7 feet. Besides these extreme variations in development, there are shades of colour from the richest Syrian purple to pure white, through every tint of blue, lavender, and grey, and equally diverse habits of growth. Let me endeavour to select a few of the more distinct in respect of

habit and colour. Amongst the blue flowers, the Russian *A. bessarabicus* stands unrivalled; closely allied, and treading on its heels in the matter of beauty, are *A. Amellus* and *cassubicus*, said by some botanists to be synonymous; but, as grown with me, certainly distinct. They differ from the former in the closer arrangement of the ray-like florets, the more compact growing of the flowers, and the regular arrangement of the blunt-pointed leaves, all along the stem; rarely does any of them exceed 2 feet in height, and seeing that they retain all their leafage in spite of the driest summers, they are an invaluable adjunct to an herbaceous border. Dare I offer them each an associate, I would at once say none is more happy and appropriate than the lively variegated *Vinca elegantissima*, with its lustrous leaves arranged along its slender and gracefully recurved stems, forming a golden-mottled setting, from which the azure stars rise with a vastly-increased charm and loveliness. Next to these in decorative value—if, indeed, it does not rival them—is that form of *A. longifolius* known by the well-merited title of *formosus*; it produces its blossoms of lovely rosy-lavender in such masses, that they altogether lose their individuality. Associate this plant with the pure white Japanese *Anemone* in a group, and you may realise the effect of the roseate tint of early dawn on the summit of a snow-capped mountain. Amongst the dense growers, there is scarcely any old garden but has its tuft or tufts of the compact *Aster dmosus*. Scarcely exceeding a foot in height, it bears a somewhat similar relation to *A. Chapmani* as does the terrier dog to the greyhound amongst the canine breed. Scarcely taller, but wonderfully graceful and airy in its contour, is *A. miser*, whose tiny little blooms are produced in myriads, and form a charming and appropriate sort of neutral tint for decorating the flower-stand at this season of the year.

The *Sikkim Aster*, though rigid in its growth, as well as in the flat panicles its blossoms present, is more rarely met with than it ought to be; looked at from a botanical point of view, it is one of the best defined species we possess. Very closely related are the following species:—*Ericoides*, *multiflorus*, and *pendulus*, the last, by its gracefully pendulous growth, completely hiding any bareness of the stems below. These all grow to a height of from 2 to 3 feet. Of similar size is the *Aster patens*; but its flowers are large light blue, and erect; its foliage is broader, and bluntly-pointed. Another group, just now coming into full bloom, may be very fittingly represented by *A. Chapmani*, consisting of closely-allied species—*viz.*, *levis*, *laxiflorus*, and *purpuratus*. These are all remarkable for a light elegance of contour, owing to the lax distribution of their slender floretted flowers, as well as the slender foot-stalks on which they are supported. *Aster rigidus* and *aspericaulis*, both good showy species, have come and gone since my last review, so I must pass on to *A. Novæ Angliæ*, whose dense panicles of rich Tyrian purple blossoms are supported on stems from 1 to 5 feet high; could we only find some means of reducing its height or preserving its stem foliage, it would be one of our finest *Asters*. Here, however, its late blooming prevents it from maturing its seeds. I have tried, unsuccessfully, to obtain some from its native country, as to that source alone can we look for any possibility of improvement. There are two deep rosy-coloured varieties of this species, called respectively *roseus* and *roseus major*; but, so distinct are they, that they are, in my opinion, deserving of specific titles. In a fine season they get with us to a height of 6 or 7 feet, and are ten days or a fortnight later in blooming. They, however, have the same defect as the primitive species as regards nakedness of stems, rendered more conspicuous by their increased height. *A. oblongifolius*, often called *bostoniensis*, though possessing much smaller flowers, has pretty twisted short leaves, largely distributed over the younger portion of the branches. The latest of all the tall *Asters* is *A. grandiflorus*, a scarce and somewhat tender plant, belonging to the south of France. It is readily recognised by its short, rigid, recurved leaves, a character which extends in a marked degree into its involucre bracts and its large dark blue flowers. *A. bessarabicus* is frequently met with in gardens under this name, but the two are widely distinct species. This plant does best at the foot of a sunny south wall, where its early spring growth ensures an early development of flowers in the autumn, and the full ripening of its underground stems. There remain yet two dwarf species I must not omit, *viz.*, *A. versicolor* and *A. pulcherrimus*; neither are more than 9 inches high; the former, as the name indicates, first produces pure white flowers, which gradually change to a rosy tint as they begin to fade. The latter has narrow linear leaves, somewhat harsh and rigid to the feel, each little branch supporting six or eight good-sized flowers. Both these species are better adapted for the rock-work than the herbaceous border.

Other Flowers of the Season.—The genus *Silphium* has still two representatives in full flower, *viz.*, *laciniatum*, the

"Compass Plant" of North America, which we usually have 12 feet in height at this season, but which has, for some cause or other, omitted to flower with us; failing the bloom, however, the curiously cut large leaves have always a distinct and special attraction. *S. Terebinthinaceum* is now, however, in such bloom as I never saw it before, with stems nearly 8 feet high, perfectly smooth and shining, rising from a cluster of quite entire leaves, each supported on a long foot-stalk. The hot, dry season, if it has affected the height of some of the late Sunflowers, has brought into nice bloom one or two that we do not often see flowering. Amongst others, the *Helianthus orgyalis*—whose slender leaves droop gracefully along the entire length of a stem 8 feet high—is decidedly improved by its terminal clusters of blossoms; *H. atrorubens*, with its dark-red stem—not flowers, as some might imagine; also *H. Hookeri* and *doronicoides*, are all strong-growing but useful late-blooming plants, adapted to either the herbaceous border or the wild garden. There is a genus called *Stevia*, of which we have several species now in bloom, that are not half sufficiently grown, and are considered by many to be tender. Amongst the more distinct and effective species are *S. ovata*, with scattered panicles of pure white little flowers; *S. ivaeifolia*, with dense masses of rosy-white blossoms; and *S. trachelioides*, with a lax arrangement of bright crimson flowers. These, as well as *S. Eupatoria*, *S. serrata*, and *S. monardefolia*, are all not only useful border plants for the second rank, but equally useful for cut flowers at this season of the year. One reason why they are considered tender is, I believe, because they are not planted sufficiently deep, and their mass of thick wiry roots rot off from the old root stock; there ought to be at least 6 inches of soil above the crown to ensure perfect immunity from frost. *Asteriscus maritimus*, sometimes called a *Bupthalmum*—though not hardy with us—has such a nice habit of growth, and flowers so abundantly through the entire season till the frost comes, that it is always worth the thought of inserting a potful or two of cuttings in the autumn, and placing the same for the winter on a greenhouse shelf; it is by no means as showy as the *Gazania*, but is still worthy of a place in the rockery—the sunnier the better, as it comes from the south of Spain and north of Africa. The same remarks apply to the pretty slender-leaved *Nejas-falcata* and *gracilis*, both Composites from the Cape, producing gay orange-yellow flowers throughout the whole summer, and always remarkably neat and elegant.

The Evening Primroses or *Oenotheras* still present a wonderful display of bloom on the biennial species, such as *O. Lamarckii*, *macrantha* and *gigantea*; the latter last year attained with us a height of fully 8 feet, but, owing to its vigorous growth, scarcely realised its full period of blossom ere the frost marred its beauty. Amongst the *Ericas*, large tufts of *E. Mackayi* are still covered with their beautiful soft rosy flowers, as are also *multiflora* and its white variety; these, however, have been somewhat earlier than usual this season. The closely allied *Menziesia polifolia* and its varieties—are almost continuously in bloom throughout the summer, and still yield charming bright-coloured sprays of either crimson or pure white flowers. On the rockery, *Anthyllis montana* is covered with blossom, for the second time this season; its dwarf compact habit and soft rosy heads of flowers render it a valuable plant. The latest of all the *Statice*s, *S. Willdenowii*, is now tipped with lovely lavender blue, at the terminal points of its somewhat scattered inflorescence. 'Tis the last of the genus for the season, and hence all the more prized. The value of many species of *Oxalis* for autumn decoration, whether in pots or on the rockery, has recently been alluded to by some of your correspondents, and well deserving is the genus to be worked up again. Many species have been lost sight of in general cultivation. *O. purpurea* had, a few days ago, blooms fully an inch across, of lovely rose, not more than 2 inches high, which, in the full sunshine of a bright autumn day, had a charming appearance; equally large, and of a similar tint of colour, though very different in habit, is *O. multiflora*; both these are, however, too tender to stand our climate, though possibly in Cornwall they might prove hardy. *O. Bowiana* is just now coming into full flower at the foot of the front wall of the greenhouse, where it has grown for years, enjoying, at the same time, the shelter of such a locality, and the perfect summer's rest, which its dryness secures. The so-called *O. floribunda*, however appropriate the name may be, is certainly, as is generally known, quite distinct from the plant figured in the *Botanical Register*; it might as well be called *sempervirens*, as it is in full bloom from May to November. The last and least of the *Oxalises* is that sometimes called *granulata*, but more correctly named *lobata*; the dense dwarf cushion of bright green leaves (only developed within the last week or two) are now enlivened with numbers of bright yellow flowers; this plant is somewhat exceptional in the genus as having its leaves composed of four leaflets in place of three. *Hypericum aegyptiacum*, though not quite hardy, is of such a neat habit, and so floriferous, that it deserves a passing note; its leaves are little bigger than a Thyme, and its little flowers are pro-

duced by hundreds. The lovely autumn Crocuses have had their day and are now past, but *Sternbergia lutea* is yet gay with yellow flowers, that remind one strangely of spring. *Sempervivum ciliatum*, owing to its affecting a considerable altitude on Teneriffe, stands well with us in a cold frame, and has the happy power of indulging its cultivator with a nice crop of intensely yellow blossoms late in the autumn as well as in early spring; it is a very distinct form of our common type of the House-leek family.—J. C. NIVEN, *Botanic Gardens, Hull*.

Kitchen Garden.

This is the best season for repairing or re-planting Box edgings. Where these are large, and have stood some time without being re-planted, it will be advisable to remove some of the exhausted soil and replace it with fresh material; in most instances this can be had from the border adjoining without incurring much extra labour. Where permanent edgings of a dead character are preferred, there is a hard blue Staffordshire brick well suited for making good, neat, durable, kitchen garden edgings; they look best when placed on end, sloping at an angle of about 30°. If cheapness is an object, any hard ordinary bricks, such as I have seen made in Sussex and elsewhere, where a similar sub-soil prevails, would do. Soft red bricks, like those commonly used for building in Norfolk, would be too porous, and would soon perish. The proper way to put in a brick or tile edging is to lay down a line along the outside limit of the path; open a trench along the reverse side the proper depth, leaving a firm perpendicular edge next the path, against which the bricks should be placed and made firm. To plant Box edgings properly requires a considerable amount of time and skill; but brick edgings may be put in with less labour by a good handy man. There is yet time to plant Cabbages to succeed the earliest lot; although, in most cases, it will perhaps be better to defer this till February, as, if we have a hard winter, they will suffer less if standing somewhat thickly in the nursery beds, in which they will afford each other mutual shelter. Any spare plants standing in seed-beds that are strong may be dibbled in thickly in some warm place, to be used as Coleworts during the winter. I prefer this plan to planting the main bed thickly, with the intention of thinning for use as the season advances; as, on retentive land, the frequent treading in thinning the crops in bad weather makes it unsuitable for the plants left. But where the stems from which the Cabbages were cut during last spring and summer are allowed to remain, and were treated to a surface mulching during the hot weather, they will now be producing sprouts, and will continue doing so through the winter; and where this crop is allowed to remain, this obviates the necessity of specially planting Coleworts. It, however, takes a good deal out of the land, as everybody will admit who has seen the amount of produce taken from a bed of Cabbage treated in this way. This, however, can easily be met by heavy dressings of manure, and by selecting a less exhausting successional crop. Our usual plan is to allow this crop to stand till the end of February, by which time the young Cabbages will be coming in and the crop will be of little further value. A very heavy dressing of decayed and charred vegetable refuse, including a proportion of burnt earth, is wheeled on the land, which is then turned up deeply and finally planted with Potatoes. I find a dressing of this kind to be of more value for invigorating an exhausted soil than stable dung. Everything in the way of useless vegetables, weeds, leaves, &c., should be frequently cleared away. Clean culture is as important (especially amongst growing crops) now as at any season of the year. Land covered with weeds or strewed with leaves or vegetable refuse, cannot derive the same advantage from atmospheric influences as where clean culture is the rule.—E. HOBDAY.

PERSONAL.

THE Rev. Reynolds Hole's garden at Caunton is being remodelled, under the direction of Mr. Marnock.—Mr. Wm. Hugh Gower retires from the Victoria Nurseries, and, we believe, from horticulture altogether.—Many of our readers will be pleased to learn that Mr. W. Thomson, of the Tweed Vineyards, is recovering from his recent very severe indisposition.—Messrs. Fletcher, Lowndes, & Co., are to erect the handsome conservatory which is to form the upper story of Messrs. Barr & Sugden's new premises in King Street, Covent Garden.—Mr. Wills is arranging a handsome conservatory for Lord Walsingham, at Merton Hall.—Mr. Meston is to carry out the works in the new parks at Birmingham and Sheffield, both of which have been designed by Mr. Marnock.—At a recent meeting of the Royal Isle of Wight Horticultural Society, the first premium for Roses was awarded to Mr. Edward Meehan, who for nearly forty years has had charge of the gardens and grounds of St. Clare. During this time he has been one of the leading exhibitors in the above society, and, with few exceptions, has taken the first premiums for Roses as a regular thing. Mr. Meehan is the father of the accomplished editor of the *American Gardeners' Monthly*.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

TREE MANAGEMENT IN AND NEAR TOWNS.

By JAMES McNAB, Royal Botanic Gardens, Edinburgh.

TREES planted in and near towns are but too frequently neglected and left to themselves as soon as the planting is over, inasmuch that their growth is to some extent impeded, and they seldom assume the regular upright form required, without considerable care. Trees for avenue lines ought to be specially trained for that purpose in nursery rows, and frequently transplanted before being transferred to their permanent places. Instead of being long and lanky, they are better to be stout and about 6 or 8 feet high. After they are thoroughly established in their new position, it is time to commence stem pruning, and branch pointing; and if such trees are properly attended to for a series of years, they will make infinitely better specimens than those planted from 8 to 10 feet in height, which certainly produce a favourable appearance at first, but generally fall behind from unavoidable causes. The contractor employed to put in and protect such plants is generally bound to uphold them for a year or so, after which period such trees pass out of his hands and are afterwards neglected. This state of matters is particularly noticeable in many of our leading cities, and chiefly in the case of trees planted within the last twenty or thirty years, but more particularly during the last ten or twelve. Many of those alluded to, although in a healthy condition, have their stems short from the want of timely upright pruning, some of their terminal leaders running strangely to one side, or having one or more of their side-branches outgrowing the rest; such extra growths should be shortened, in order to encourage a proper development of the tree. All through the southern suburbs of Dublin, newly arranged for streets, trees have been extensively planted along the edges of footpaths, and although all are in a free-growing healthy condition, the want of branch and stem-pruning at the proper time has caused them to assume rather a wide-spread appearance, the stems being shorter than they ought to be, and the tops, although healthy, very much dwarfed. The same remarks are applicable to many of the trees under the management of the municipal authorities of other cities, as well as those now to be seen in many suburban villa gardens. In the latter, the proprietors plant freely at first, for the purpose of screening or sheltering their houses, and the result is that many such residences are now so thickly surrounded with trees as to render the atmosphere about them close and unhealthy. Few of the proprietors seem inclined to thin out even the original-planted nurse-trees, such as Poplars, Willows, &c., from the fear of opening up their grounds too much, and thus becoming overlooked by their neighbours. In consequence of this, complaints are rife as to trees overhanging adjoining gardens. In some cases the offending branches are cut off, and a pitiful appearance is then presented to the complainant, worse even than the original intrusion. It would be frequently better to have such trees removed altogether or pollarded, when new-made side-branches would be abundantly produced, and might be afterwards pointed, and kept within proper bounds. The state of matters alluded to is every year becoming more and more a source of annoyance, and worse to remedy. All trees, both old and young, under municipal control, ought to be put under the management of a properly certificated forester, instead of committing them to the mercy of anyone whom the municipal powers for the time being may choose to call in to attend to them, and this often after mischief has been done, not unfrequently by parties who possessed but a very indifferent knowledge of pruning operations. Unless an experienced inspector is often amongst such trees, and observing from time to time the requirements necessary for their preservation, it will be difficult to get them kept in the condition in which they ought to be. Many large trees are found in a decaying

condition from the want of surface-dressing at the proper time; this duty should also devolve on the forester. Municipal authorities would, perhaps, not have sufficient work to fully engage the services of an experienced forester, but any spare time might be advantageously employed at a certain remunerative rate by the directors of town squares and cemeteries, and also by the proprietors of suburban villa gardens. Town squares or enclosures are generally under the management of joint proprietors, whose duty it is to suggest and attend to the necessary pruning and thinning, but if one of the proprietors should take an over-interest in getting such work accomplished, it is generally considered to be for some selfish end, and his views are not, therefore, endorsed by others; when, if it were possible to employ the services of a competent city forester, such things would go on smoothly. In country districts, the hedge-row trees are generally seen in good condition, as they are or ought to be attended to by the forester employed on the estate through which such roads pass. The manipulation requisite for the management of forest and ornamental trees in towns is frequently entrusted to gardeners, who naturally fall into the management of such work; but they often do not possess that scientific arboricultural knowledge which has from long practice been acquired by a thorough-bred forester; the latter knows the time and method of pruning, both of old and young trees, so as to prevent that internal injury which too often befalls them; and, for securing the proper development of trees in after years, he is the proper person to employ for such work.

KENSINGTON GARDENS.

WHILE in Kensington Gardens the other day, two or three matters occurred to us on which it may be useful to say a few words. Entering at the small gate at the corner of Kensington High Street, opposite Mr. Albert Grant's new "palatial residence," we found the superintendent's house levelled with the ground, green turf in its place, with a stont iron railing separating it from the high road, instead of the dull piece of high dirty brick wall, which has existed there for many years. We drew attention not long ago, to the rumour that this change was about to take place, at the solicitation of Mr. Albert Grant, who, for the sake of obtaining a better view from his house, was said to have offered to be at the expense of the alteration. We felt a moment's distrust of the propriety of acceding to such a proposition, because, if private solicitation is once allowed to affect the disposal of public property, it is difficult to draw the line where legitimate arrangement ends, and undue influence begins. This is, however, undoubtedly a matter in which a certain amount of discretion must be allowed, but one in which its exercise should be closely scrutinised. Now that we have seen the result of the alteration, we have only to congratulate the authorities on having accepted the proposition; that is, supposing the rumour referred to to have been true. In all respects the alteration is a decided improvement. Whatever diminishes masonry and adds to vegetation in and about London, and more especially in our public parks, must be an improvement. For this reason we have always sympathised with the few reclamant voices, which, at the time, protested against the introduction of Captain Speke's obelisk into Kensington Gardens. All honour to the well-deserving, but let their deserts be recognised in suitable places. There is no need for forming a new Kensal Green in one of the few pieces of greenery of which we Londoners can boast. If not too late, may we ask, Is there no public square or open space, where stone and mortar are not out of place, into which it could be removed? There is the excellent precedent of the removal of Jenner's statue from another part of the gardens. Other instances of bad taste in these gardens are neither few nor unimportant; but what distresses us most is the lamentable fact that the decay of the trees in them goes on with increasing rapidity, and that no steps are being taken to replace them; for anything short of re-planting would now be ineffectual. With every care and economy the cost of such alterations must be great, but so is the object to be attained; and we feel sure that any expense in the preservation of Kensington Gardens as a sylvan retreat for the London public will be cheerfully met.

A. M.

NOTES OF THE WEEK.

— THE *Phylloxera*, we hear, has made its appearance among us in several ranges of Vineries, the Vines in some of which have had to be uprooted and destroyed, a fact which deserves the most serious consideration. There seems to be a reluctance among gardeners to admit that they have got it on their Vines; but, if something is not done at once to stamp it out, it will, by-and-bye, be impossible to do so. It is, therefore, exceedingly important that any case of *Phylloxera*, whether in a private or public establishment, should be made known, if any practical measures are to be adopted for its extermination. It has been suggested, as a means of staying its ravages in France, that instead of introducing American Vines, the wild Vines, abundant in many parts of that country, should be carefully cultivated; they produce, in a wild state, excellent fruit, and as they are very hardy, it is thought they would withstand the attacks of this pest.

— We learn from a recent visitor to Vienna, that the flower-beds in front of the restaurants of the Staltpark, have, this summer, exceeded in splendour of colour and arrangement, anything of the kind which has been seen this season in any other part of Europe, not even excepting the public gardens of Paris, or its famous Parc Monceau, or the parterres of Versailles; we also learn from the same source, that the populace of Vienna displays a respect and appreciation for works created expressly for popular enjoyment, which is not found to the same extent, in any other capital.

— THE Rev. Reynolds Hole writes to us to say that he quite agrees with Mr. Davison, of Hereford, as to the merits of the Rose President Thiers, the claims of which adverse seasons have obscured to some extent. He also suggests that those who protest so vehemently against the present arrangement of Rose shows should have a space allotted to them at some of our great shows for the illustration of their ideas on the subject. This course would be more instructive than a long and wordy discussion.

— LIVERPOOL, we think, is to have an aquarium and winter garden on an extensive scale. The latter is to be constructed principally of glass, according to a plan furnished by Mr. Rendle, and is to form, in fact, a large and handsome conservatory, in which are to be choice plants, fountains, and statuary, as in the Crystal Palace at Sydenham. Amongst other special attractions, too, is to be a large Fernery, arranged with a view to the most pleasing effects. Flower shows are also spoken of as forming part of the contemplated arrangements.

— MR. JOHN HORNE, of the Botanic Garden, Mauritius, who is now on a botanical expedition in the Seychelles, says (writing to Dr. Hooker) that he has visited the islands of Silhouette, Praslin, and Félicité, searching them from the sea-shore to the tops of the highest hills in Silhouette up to 2,200 feet, at which elevation Pitcher plants abound, hanging in immense clusters over every stone, bush, and tree. Flowers of these *Nepenthes* were obtained, and arrangements made for procuring a good supply of plants. When these materials come to hand it will be seen whether the *Nepenthes* of Silhouette is different from the *N. Wardii* which grows in Malacca. The tops of these mountains, where the Pitcher plants grow, have a perpetual moisture hanging over them, being almost constantly enveloped by mist and rain.

— THE boulevards of Vienna are more spacious than those of Paris. In the more important parts they are about 160 feet wide, and thus divided—the paved footpaths on each side are 18 feet wide; adjoining them, on each side, are paved roadways for heavy traffic 20 feet wide; next come, on each side, loose gravel roads, bordered with trees, for equestrians. The trees are, in some places, Oriental Planes and *Ailantus glandulosa*, alternately. In other places they are Horse Chestnut and *Robinia Pseud-Acacia*, all of which, from the favourable nature of the soil, are doing well. The poor Unter den Linden of Berlin, and even the drives and promenades along our own Thames Embankment are vastly inferior, both in plan and dimensions to this spacious stretch of Viennese boulevard.

— MR. DAVID THOMSON informs us that there are at present 250 spikes of *Calanthes* in bloom in the Orchid-house at Drumlanrig, besides others removed for indoor decoration in the castle and what have been sent for various purposes. The varieties grown there are *C. vestita rubra*, *C. v. lutea oculata*, *C. v. lutea flava*, and *C. Veitchii*. Many of the spikes are over 2 feet long, not including the stem of the spike. At a season when not many Orchids are in bloom, and when flowers generally are most scarce, these are invaluable; when cut and placed in sitting-rooms the spikes remain fresh, and continue to expand the whole of their upper blooms for more than a month. As a rule *Calanthes* are starved. See what immense bulbs they have to form in a few months. That ought to be an index to the kind of treatment they require; the soil they are grown in at Drumlanrig is composed of the most fibry peat, a very little loam, a good proportion of horse droppings in a dry state, and a little Sphagnum. When the

plants are in full growth they are watered frequently with guano water. *C. v. lutea oculata* is a much finer variety than *lutea flava*; it is white, and nearly double the size of that kind; consequently, *flava* is not worth growing where there is plenty of *oculata*.

— SEVERAL nice Orchids are now in flower at Messrs Veitch's, foremost amongst which may be mentioned the rare and beautiful *Oncidium Rogersi*, on which more than 100 flowers are now open. In the same establishment *Maslevallia tovarensis* is also bearing twenty-seven flowers. This is one of the best of winter-blooming Orchids.

— SEEDS of Weigelas were sown by M. Carrière in the spring of the present year. More than two hundred of the seedling plants flowered during the month of August, just as might have been the case with ordinary annuals. The plants were extremely small, scarcely 1½ inch high; yet most of these dwarf plants exhibited marked differences both in the form and colour of the flowers.

— *HYDRANGEA ACUMINATA* has proved itself to be a very handsome and highly desirable plant. It is, according to M. Carrière, the most beautiful species of the entire genus. Placed in a shady position, the flowers remained in perfection for a considerable time, and it bears the sun much better than any other species.

— We learn that the exhibition of insects injurious to trees and garden plants, which was held in the Orangery of the Tuileries Gardens has just closed. The distribution of prizes took place on the 5th. The highest premium was awarded to a Viennese Savant, for a magnificent atlas, exhibiting all the organs and forms of the *Phylloxera*. Yet the *Phylloxera* question is still left open, which is discouraging. The exhibition, which lasted twelve days, was very popular; 20,000 persons paid the entrance fees, and 30,000 free tickets were issued.

— THE recent autumnal Rose show at Lyons, to which we have previously adverted, surpassed the most sanguine hopes of its projectors by its brilliancy, and by the interest which it excited. For many years autumnal Roses have not been seen in such perfection as they have been this season. It is superfluous to speak of the distribution of prizes, further than to say that M. Luvet carried off the gold medal, and that a first-class silver medal was also awarded to him for a magnificent yellow seedling Tea Rose, which is to be called *Perle des Jardins*—a fit associate, it is said, for *Maréchal Niel*.

— AN extremely beautiful Apple, called *Belle de Lippe*, is figured in the Belgian *Bulletin d'Arboriculture*, for the present month. The coloured plate devoted to it is one of the brightest and most successful specimens of chromo-lithography that we have seen. This beautiful Apple appears to have been extensively grown for more than half-a-century in the orchards of St. Trond, which forms one of the most important centres of the vast fruit trade of Belgium. It is said that this variety was originally received in a bundle of grafts from Normandy, where, however, it must have become extinct, as it is not to be found in the Norman orchards of the present day. The fruit merchants of St. Trond hold this variety in high esteem, as perhaps the very best of the class *Court Pendu*, or short stalks. It is also a very prolific bearer.

— FOR our London balconies and window sills, which have displayed since early spring such an abundance of gay floral colours, we are now reduced to a very restricted choice. We have arrived at the beginning of that long wintry season, during which evergreens, especially those which bear brightly coloured berries, must take the place of *Lobelias*, *Pelargoniums*, *Tropeæolums*, and even *Mignonette* and *Stocks*. There is, however, a short transition period, during which the gay colours of the late flowering *Chrysanthemums*, or one or two of the hardiest autumn-flowering *Cyclamens*, may be made to alternate well with the brightly mottled leaves of the *Aucuba*, and still, for a time, make our window sills pleasant, and even gay; but during the months soon about to follow, our decorations in the way of plants must be confined to *Euonymuses*, *Box*, shrubby *Veronicas*, and similar plants, which must suffice till spring once more brings round the time of *Crocuses*, *Snowdrops*, and *Primroses*.

— MANY natural productions destined to produce great results in various branches of the arts, appear, on their first discovery, to be of small importance; and it is only by slow degrees that their real value becomes known. For fifty years after its discovery, *Caoutchouc* only served the purpose of effacing superfluous lines drawn by the black-lead pencil, while at the present time it has become a product of the first rank, its application to various purposes having given to its collection and importation a great and constantly increasing value; and it has led to the erection of industrial establishments on a vast scale, which give employment to hundreds of skilled workmen. The same may be said of guano: when first noticed and described by Humboldt in 1804, it figured soley as a ticketed and numbered specimen in museums. It was not till 1841, that M. Bosch-Spencer, Belgian Consul, at Lima, sent the first cargo to Europe, and now the revenues arising from it to the Peruvian Government amount to sixty millions of francs a year.

THE FLOWER GARDEN.

ROSE CUTTINGS STRUCK IN WATER.

SELDOM do we see Roses well grown on their own roots, and yet what freshness and beauty do we occasionally find among Roses grown in that way? What is more beautiful during summer than a bed of Roses, the shoots of which have been pegged down, so as to make the whole represent a mass of well-developed buds and fragrant flowers? Roses too, look well in the form of a hedge, and, as I write, I have "in my mind's eye," a hedge of Gloire de Dijon, on which there is every year abundance of pale fawn-coloured flowers, and stout waxy foliage, from May to November. This Rose is, in this instance, on its own roots. Rose cuttings strike readily, especially such as belong to the hardier and strongest growing kinds. Our illustration represents a mode of striking cuttings of this kind in bottles of soft water, a plan as simple as it is practicable, inasmuch, as cuttings taken off at any time during the summer, will root in this way in from five to six weeks, after which they should be potted carefully and placed in a close frame for a week or so until they have become established, when they are quite ready for planting out in either beds or borders. The bottles may be of any convenient size, and may be placed on shelves in the greenhouse, in a frame, or even in a sitting-room window, the attention they require being less than that bestowed on cuttings inserted in pots in the usual way. Rose cuttings may also be struck in pots filled with moist Sphagnum Moss. Even eyes separated, as if for budding, but having a little more wood attached to them, may be rooted with facility in pans of light earth surfaced with sand; I have often resorted to this practice in the case of new or rare kinds, and it is astonishing how robust and vigorous the plants raised in this manner become. As regards striking in water, I have tried Hybrid Perpetuals, Teas, and Bourbons in that way, and all have rooted freely; and I have some fine specimens of plants raised in this way. As to Manetti stocks, cuttings may be planted now. Procure some strong shoots, a foot or 13 inches long, and carefully remove all buds except the three top ones, which should

be left to draw up the sap, and plant them in rows 18 inches apart, and 1 foot asunder in the row. Prepare the ground well before planting, which should be done with a spade, with which a trench should be cut for each row. In planting, place a little mixed sandy loam and leaf mould at the base of the cuttings, taking care to tread them in firmly, leaving the three buds out of the ground. If the cuttings do well, and are good and strong, they will be fit for budding the following season. If the winter is severe, it is advisable to protect a little, by means of some long strawy litter shaken over the beds. Those who wish to plant a few Briar stocks for budding the following season, will be able to obtain some at the present time, as Briars may now be had; care should be taken, however, not to allow their roots to get frosted. Plant in rows, allowing a foot between each stock. If a quantity is required to be planted, put them in in double lines, allowing 18 inches between the two rows, and 2 feet between each set of double rows, so as to afford room for budding. The root of the Briar requires careful pruning, in order to remove all spurious wood and bruised bark, leaving a neat club root; by so doing, stocks of this kind will certainly callus and root very much quicker than when they are not properly root-pruned, an operation to which all Briar stocks should be subjected before they are planted. H. G.

Rose cuttings struck in water.

CULTIVATION OF THE HOLLYHOCK.

HOLLYHOCKS require good garden soil, well trenched to the depth of 2 feet, and plenty of thoroughly decomposed manure, such as that from old Cucumber beds. A wet sub-soil is good in summer, but in winter is injurious to them, and to prevent surface wet injuring old plants left in the open ground I remove the mould round their necks, and fill up with about 6 inches of white sand. This preserves the crowns from wet. It is best, however, to plant young plants every year, as one would Dahlias, i.e. if fine flowers are desired. Hollyhocks may be propagated by means of single eyes put in in July and August, and also by cuttings put in in the spring, on a slight bottom-heat. Plants raised in summer, are best preserved by re-potting in October into large pots—the larger the better, in light rich sandy earth, and placing them in a cold frame or greenhouse, giving them plenty of air on all favourable occasions. Thus treated they will grow a little during the winter. In March or April turn them out into the open ground, and they will bloom as finely and as early as if they had been planted in autumn. Plants even put out in May will flower the same year. Plant them not less than 4 feet row from row, and 3 feet apart in the row—if grouped in beds, not nearer than 3 feet each way. In May or June when the spikes have grown a foot high, thin them out according to the strength of the plant; if well established and very strong, leave four spikes; if weak two or three. When they are required for exhibition, only one spike must be left. Stake them before they get too high, tying them securely, so as to induce them to grow erect. The most

robust among them will not require a stake higher than 4 feet above the ground level. If the weather is dry they may be watered with a solution of guano, or any other liquid manure poured carefully round the roots, but not on or too near the stem. If fine blooms are required cut off the lateral shoots, thin the flower buds if crowded together, and remove the top of the spike, according to the height desired, taking into consideration the usual height and habit of the plant. By topping be it observed, you increase the size of the flower, but at the same time shorten its duration, and perhaps disfigure the appearance of the plant. The best way of showing Hollyhocks is in the form of spikes, and in judging, the first point should be the individual flowers, the perfection of which consists in the petals being of good substance; while the edges should be smooth and even; and the florets occupying the centre, full and compact, closely arranged, rising high in the middle, and of a globular form, with a stiff guard petal extending about half an inch, or in proportion to the size of the centre ball,

so that the different parts of the flower may present a uniform appearance. The next point should be the arrangement of the flowers on the spike; they should be regular, not crowded together in a confused mass, nor hanging loosely with open spaces between each flower, but so disposed that the shape of each, when fully blown, may be distinctly seen, the uppermost covering the top of the spike. A few small green leaves between the flowers, also give an improved appearance. The third point is colour—the brightest, strongest, and most distinct should stand first, but as it is desirable to obtain shades of all kinds anything new or distinct in this way should be encouraged.

Saffron Walden.

WILLIAM CHATER.

VIOLAS AS BEDDING PLANTS.

THE improved varieties of the Viola now in cultivation must, in future, occupy a prominent position amongst bedding plants, as nothing can surpass them in richness of colour or in general effectiveness. Independently of their continuous free-flowering habit, they are specially commendable on account of their perfect hardiness of constitution and the facility with which they can be increased and wintered; although, however, they stand over winter uninjured in the open ground, and are capable of being divided and increased to any extent during the spring months, I would recommend that cuttings of them be propagated in a cold frame during this month, when every cutting will be sure to root, if put

into a light sandy compost. Thus, with the least possible labour or after attention, we secure a fresh batch of vigorous plants, which will be found to be more satisfactory than divisions. The flowering shoots should be pinched back early in the season, and, afterwards, the plants may be put out upon a border at greater distances apart, until such time as the beds are in readiness for their reception. It is important that these *Violas* should be established in their summer quarters as early in the season as possible, consistently with the removal of spring blooming plants. They naturally delight in a rather strong, rich, moist soil; it will, therefore, be necessary, more particularly in the case of light sandy soils, to secure these conditions for them by introducing fresh turfy soil, enriched with decayed manure, and watering with liquid manure, so as to promote vigour of growth and consequent continuity of bloom. By thus keeping the plants in a healthy growing state they seldom suffer from insect pests or mildew; but, if the latter should attack them, it may be kept in check by dusting with flowers of sulphur. There is now in cultivation a large variety of *Violas*, many of which possess features of considerable merit. I have found the best to be *Viola lutea grandiflora*, a tall free-blooming kind, good for centre groups; Dickson's Golden Gem, the finest of the yellow class; Cornuta var. Magnificent, a handsome purple variety; C. var. Sensation, deep blue, a good bedder; C. var. Perfection, a well-known variety, possessing good properties as a bedding plant; Blue Bell, a charming variety, resembling, to some extent, *Viola Perfection*. Its blossoms are shaded violet, and the plants, though remarkably compact in growth, are vigorous in constitution, withstanding attacks from mildew better than *Perfection*. Blue Bell comes into bloom early in the season, and remains in beauty till late in autumn. It is, therefore, a variety which cannot fail to give satisfaction.

Witley Court, Southampton.

GEO. WESTLAND.

Hardy Flowers in France and at Home.—I have had a very enjoyable tour in France. I visited the Botanical Gardens at Amiens, Paris, Chartres, Angers, Tours, Caen, Rouen. At all of them I met with something special and good, and at all I met with kindness and civility. I also got much "spoils." At Angers, M. Boreau was very kind, and gave me a quantity of good Sedums. I think the plants that most struck me were the herbaceous *Hibisci*—*militaris*, *moscheutos*, *grandiflora*, &c., which were magnificent. I made the acquaintance of what I think one of the best rock-work shrubs I have seen, viz., *Atraphaxis spinosa*; I saw it first on the low banks of the Bois de Bonlogne, and afterwards I saw it elsewhere. I came to the conclusion that the French gardeners are infinitely ahead of us in ornamental summer gardening. I have never seen anything in England to come near the Park de Monceau at Paris, and the Bosquet du Roi, at Versailles. It was miserable after them to see the strip near Park Lane, with its everlasting *Scarlet Geraniums* and *Golden Pyrethrum*. At home here I have some good things still out in the garden, and no lack of flowers. I specially note *Tritonia aurantiaca*, *Convolvulus Scammonia*, *Exogonium Purga*, *Anemone japonica*, *Crocus*, and *Colchicum* of many sorts, *Belladonna Lilies* (never finer than this year), *Solanum jasminoides*, *Erythrina laurifolia*, *Abutilon vexillarium*, *Fuchsias*, *Roses*, and *Asters* in abundance; and among botanical curiosities are *Rosecea purpurea* and *Jaborosa integrifolia*. Among the *Roses* now out, there is none to beat the old single *Macartney* and *Aimée Vibert*.—H. N. ELIACOMBE, *Bilton Rectory, near Bristol*.

Free Flowering Cannas.—These ought to be more universally known than they are; for amongst sub-tropical plants none are more effective, especially if planted according to heights and colours which are given below, in three classes. In the first class I will place the dwarfest, in the second those of the middle height, and in the third the tallest. Of the new varieties of the past three years all are not so ornamental in foliage, as some of the older kinds, but they are invaluable on account of their flowers, which, in some varieties, nearly approach those of the *Gladioli* in beauty. One of the finest sub-tropical beds I have seen this season consisted of *Cannas*, most of which are free-flowering varieties. The outside row was planted with *Prince Imperial* and *Bihorelli*, the first of which bears fine spikes of bright scarlet; the latter orange-scarlet. In the centre were patches of *Pemice de Nice*, a fine clear canary yellow coloured kind, and *Van Houttei*, a bright orange-red. This bed was belted with *Tussilago Fackera variegata*; and the dark red shade, and two shades of green of the *Canna*, together with the soft sulphur margin of the *Tussilago* gave to the whole a charming effect. Flowering *Cannas* are also of great use in autumn, for if taken from the ground with a good ball of earth, potted, and given one good watering, they will make a fine show of flower for some time when placed in the conservatory or greenhouse. After they have done blooming, they may be cut down to within 3 inches of the bottom, and placed

in any dry cool situation for the winter. In the first class I would place *Prince Imperial*, bright scarlet; *Bihorelli*, orange-scarlet; *Bihorelli elegans*, indian-yellow; *Bihorelli splendens*, bright scarlet; *Michel Bonnett*, bright crimson; *Gustave Bonnett*, orange-scarlet; *Mulleri*, crimson; *grandiflora floribunda*, orange; *compacta*, yellow, spotted red; *Ferrandi*, bright crimson. In the second class *Senateur Chereau*, yellow, with red spots; *lutescens*, yellow; *Imperator*, dark scarlet, orange-spotted; *gigantea floribunda*, orange-buff; *rotundifolia rubra*, orange; *Picturata fastuosa*, light yellow, spotted red. In the third class *Pemice de Nice*, canary yellow; *Auguste Ferrier* scarlet and orange; *Rendatleri*, orange-buff; *Deputé Henon*, yellow and rosy-red, shaded; *Ernest Benary*, orange-red; *Van Houttei*, bright orange-red. There are several other flowering varieties; but they are either too early or too late, so I omit them in this selection.—R. H. B.

Mixed Annuals Sown in Front of the Shrubberies in Kensington Gardens.—In the early part of the season we had an opportunity of noticing the natural and pleasing effect produced by the sowing of mixed annuals over large spaces in front of and even in the shrubberies in Kensington Gardens. The earlier flowering kinds have now done their work of beauty, and have shrunk out of sight, making room for the gorgeous crimson and scarlet of the *Love-lies-bleeding* and *Prince's Feather* (*Amarantus caudatus* and *A. hypochondriacus*). These are half hardy plants, but they accommodate themselves so well to our northern climate, that they flourish luxuriantly with us in the open garden, even in "chill October," filling the borders in which they abound with a glow of warm and splendid colour, which is very grateful at this late period of the year. The spaces in front of the shrubberies at Kensington, all aglow with the fiery crimson of these late-flowering annuals, are pleasant to look at just now, as affording a last glimpse of floral beauty when nearly all other flowering plants have withered and passed away. In some places, where these plants are bent down in tangled profusion by the weight of their grand close racemes of crimson apetalous flowers, their aspect is very charming.

WARE'S DOUBLE SWEET WILLIAM.

(*DIANTHUS BARBATUS MAGNIFICUS*.)

THIS pretty Sweet William grows about 12 inches in height and about as much in width. Its flowers are very double and fragrant. During winter even it is conspicuous on account of its round tufts of reddish-coloured leaves. It commences to flower early in June, and continues in blossom until the latter end of September. The mode of propagating is not at all difficult; during the summer months the side shoots may be pulled off and dibbled into some shady spot, and when rooted they may be planted out into their permanent quarters; there let them remain until the following season, when you may again commence propagating as before, *i.e.*, if more plants are wanted.

Single varieties of Sweet William.

Like the Stock and the Wallflower, the Sweet William, even in a single state, finds a place in every garden. It requires but the smallest possible amount of care to produce it in its greatest beauty. If the soil in which it is planted be but fairly good, it will grow and bloom in perfection without any trouble, requiring no special attention; not even the help of a stick to support its heads of bloom. To get the Sweet William in fine form fresh seedlings should be raised every year; the seed should be sown in the open ground thinly, early in May; by so doing it germinates rapidly under the influence of the summer's increasing heat, and comparatively large plants are thus ready for planting out in the autumn. If, however, the seed be sown in a box or pan, or in any confined space, the seedlings should be planted out into some vacant piece of ground as soon as they are large enough to be moved with safety, and then they may be transferred to their permanent places at leisure in autumn. Plants that are intended for the mixed border ought to be very strong before planting out, so as to throw up numerous heads of flower, which will support each other against rain and wind, while small plants throw up one head only, which is almost sure to be broken, unless supported by means of a stick, and tied. Like all plants that produce compact heads of bloom, the Sweet William is most effective when grown in a mass, as then the peculiar evenness of height and flatness of truss that characterise it, are seen to the best advantage. A large bed of it produces a grand effect; scarcely two plants having flowers exactly alike as regards markings, but all equal in size of truss and roundness of pip. Such a bed is worth a long journey to see, and would create no small enthusiasm in the minds of many who have, under the influences of bedding out and other specialities of plant

growth, almost forgotten the existence of the Sweet William and other old favourites. There are several forms of Sweet William in cultivation, the finest being a strain that is a sort of fusion of the old Auricula-eyed and Hunt's well-known variety. Both of these kinds produce large heads of bloom, the Auricula-eyed having, in every case, a distinct white eye, with a margin of some dark colour; but most of the flowers are what is known as saw-edged, that is, jagged and uneven in outline, a great drawback, and one which materially detracts from their beauty. Hunt's strain produces large pips of varied colours, few having white eyes, but most of them have fairly smooth edges. A good combination of these strains now furnishes fine varieties, without these defects, the pips being larger than a shilling; they are produced in large trusses, and of the most varied hues of colour. Usually, this combination produces a majority of light flowers, dark ones being the exception. As a rule, also, the dark-

Double Sweet William.

coloured flowers are smaller and inferior in quality to light ones; but no doubt they are amenable to careful selection, and probably will be improved and become equally good very shortly. A. D.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Double-flowered Variety of *Lobelia pumila*.—This has been one mass of bloom here all through the summer, and the admiration of everybody. Gardeners in our neighbourhood are daily applying for old plants, in order to get a stock of it for next season—a sure sign that its value is appreciated.—RICHARD NISBET, *Aswarby Park*.

An Effective Flower Bed.—I have seen large numbers of flower beds in many different places this season, but the most simple and striking of them all, in my opinion, was one which I saw at Burchley some three weeks ago. It was diamond shaped, thickly edged with *Iresine Lindeni*, a band of which also crossed from each corner to the centre; the divisions thus formed were filled with *Calceolaria aurea Boribunda*, whose large heads, slightly elevated above the pinched-in *Iresine*, gave the whole quite a charming and striking appearance.—JOHN ADAMS.

A Selection of Roses for a small Rosary.—As I am about planting a small rosary, I shall be obliged if you will let me know the names of a few of the choicest Roses for half-standards and standards, for the southern suburbs of London.—A. J. P. [Try Alfred Colomb, Maréchal Niel, Charles Lefebvre, Madame Rothschild, La France, Louis Van Houtte, Madame Victor Verdier, Comtesse d'Oxford, John Hopper, Duke of Edinburgh, Schœneur Vaisse, Pierre Notting, Mlle. Marie Raby, Maurice Bernardin, Victor Verdier, Souvenir de Malmaison, Général Jacquemont, Mrs. Rivers, Marie Baumann, and Xavier Olibo.]

Plants Existing Under Difficulties.—In a piece of rock-work here, we have a large mass of flint, on the top of which an Elder bush is growing in a small fissure, not wider than the blade of an ordinary pruning knife, and containing apparently no soil, the only means of sustenance being derived from rain, or from moisture condensed by the cold stone. The amount of growth is, of course, comparatively little; indeed, in five years the bush has not grown more than 1 foot in height. During the last drought it was apparently less affected than plants more favourably situated. The importance of stones in collecting and retaining moisture, therefore, can scarcely, I think, be over-rated.—J. GROOM, *Henham*.

***Antirrhinum numidicum*.**—Having had the curiosity to obtain seed of this so-called novelty, announced last autumn with a flourish of trumpets by a Continental firm located not far from the Mediterranean, it may interest some of your readers to learn that it proved to be a very old acquaintance indeed, viz., *Linaria triphylla*! The practice of introducing an old plant under a new and incorrect name is itself deserving severe reprobation, but in this case the fraud is aggravated by the grossly exaggerated description given of the plant, and under which, no one would recognise the woody *Tonilax* just named. It is described as rivaling, if not exceeding in beauty the finest *Pentstemons*! How far that description applies to *Linaria triphylla*, many of your readers can judge for themselves.—W. THOMPSON, *Ipswich*.

THE FRUIT GARDEN.

ARRANGEMENT OF FRUIT FOR DESSERT.

I HEARTILY commend the remarks of your correspondent "W. T. P." (see p. 267), to the consideration of all interested in dishing up fruit for dessert, especially to secretaries of societies, who will shortly be engaged in framing prize lists for next year's exhibitions. This, I believe, would be the means of bringing the matter fully before the public. The arrangement of flowers on dinner tables has received much attention; but fruit comparatively little; and yet fruit is of even more importance than flowers, inasmuch as it is intended to gratify the taste as well as please the eye. The proper way to gather fruit with the stalk attached to it, simple as it is, is not so well known as it should be; I speak, of course, of small fruit, and this is a point to which young gardeners should pay attention. What grand dishes of fruit have been disfigured or spoilt between the garden and the dinner-table! I have frequently taken studious care to prevent fingers from touching the fruit, so that it might appear on the table in its best condition, and how mortified have I been afterwards to find it ruined through handling. I allude more particularly to Strawberries; but the same thing has happened with Raspberries, Currants, and with almost every kind of fruit. What are termed soft fruits ought to be gathered without the least touch of the finger as far as the fruits are concerned, and they should also be gathered quickly. With high-class fruit, for which a high price is expected, it would be money well spent to pay unskilful gatherers to stay outside the garden. When a boy (yes, and a very small one too), I had to be amongst the Strawberry beds, covered with dew, by four o'clock in the morning; one learns quickly when young, and I soon learned how to pick Strawberries. Simple as the operation is, however, I am not sure what words to employ in order to make it intelligible to others. Do you know how to cut a wire with pliers? if not, turn your fore-finger and the sharp nail of your thumb into the stalk of the Strawberry dexterously, and you will have learned the whole process; take the fruit in the hand just as one does a young shoot when pinching it: do it as if handling the "apple of your eye." The calyx forms ample protection, and if the finger and thumb are gently placed behind it, and the stem cleverly nipped, the fruit may be placed in the basket without a finger bruise of any kind. The great fault consists in fruit having to be changed many times after gathering, thus rendering useless all care taken with it in that operation. What we want is some vessel in which to gather the fruit and place it on the table, and then to hand it round, which would be a very good plan. What, however, would be better still, would be to have the dessert placed in small quantities on the table after all joints had been removed. We must, however, first get out of our heads the necessity of having huge ugly formal pyramids of fruit. On the contrary, as with flowers, let us fall back to the good old-fashioned plan of arrangement, one in which mathematical exactness is dispensed with. I have said that fruit should be served at table in the same vessel in which it is placed when gathered. We cannot, however, expect to have costly china or glass dishes or stands in which to gather it; but we might have an ornamental contrivance of a commoner kind that would fit into a more costly service. I want to go one step further, and say that no one but the gardener should be allowed to have anything to do with the fruit, which should be placed by him on the dining-room table, where the dishes should be set, and in them he should place the fruit. One most important matter about which I wish to speak, is that of trimming and garnishing, which at first seems of little moment, yet, when looked into, becomes a serious consideration; for, be the flavour of some kinds of fruit ever so good, it is easily spoilt by being placed in contact with strongly-scented leaves. I have seen Laurel-leaves, Bay-leaves, Kale, and a score of other things, used for this purpose, all of which cannot be too strongly condemned; in fact, any leaves that give off odour of any kind are unfit for garnishing. But, if scented foliage is unfit for association with fruit, what shall I say in regard to odoriferous flowers? A fruit is prized for its own flavour; why then spoil it with that of either leaves or flowers?

Hardwicke Grange.

JOHN TAYLOR.

THE INDOOR GARDEN.

TREATMENT OF BROMELIACEOUS PLANTS.

Could you kindly give me a little instruction on the culture of such plants as *Billbergia*, *Nidularium*, *Vriesia*, and others of that class? Please to answer specially the following questions, concerning which I can find no such information as I desire.—G. W. CHEESMAN, *Ansonia, Connecticut*. 1. Do they ever flower a second time from the same growth?—To this question we answer no: but in the case of *Vriesias* the old growth must be left, as the new shoots come from the axils of the leaves. When the new growth is half-grown, the old leaves may be removed, and if two or three growths make their appearance, split the stem down, and let each have some portion of the roots. All young plants should be potted in small pots firmly. 2. As they bloom much finer singly, and if they only flower from the new growth, when should the young plants be removed from the parent stock to most quickly make blooming plants? when small? or when full grown?—Single plants flower and look best—a remark which applies more expressly to *Billbergias*, *Guzmannias*, *Nidulariums*, *Echmeas*, and *Encholiriums*. The young growth of some of the *Tillandsias* and *Pitcairnias* is almost fully developed before the old plant flowers. In this case it is better to cut the old growth away and leave the new; in that case, it is unnecessary to re-pot every season; otherwise, let the young growth remain until it is half grown, when it will be making roots on its own account. If taken off, and kept in heat, it will flower the next season. 3. When should they be rested?—They do best when kept growing all the year round; thus treated, they never miss flowering. 4. If they only flower from their new growth, should the old growth be removed after the new growth is started, and, if so, when the new growth is small or matured?—The answer to this question is embodied in that given under question 2. 5. Do they thrive best in the sun, or somewhat shaded?—They will do exposed to the sun; but, as they naturally grow in dense shade, they succeed best shaded, with the exception of *Dyckias* and what the Germans call *Hectias*. These like sunshine, but will do very well treated as the others. The best soil for them is three parts turfy peat, one part very turfy loam, and one of silver sand, and a free mixture of burnt ballast. To this their roots cling with seeming fondness. With the exception of the larger-growing kinds, viz., *Puya grandiflora*, *P. chilensis*, *Pourretia coarctata*, and *Greigia spheacolata*, Bromeliaceous plants are all fond of heat, moisture, and slight shade. Even *Dyckias*, though they will do very well in a greenhouse, do better in a stove. It may be mentioned that because these plants will withstand a good deal of ill usage, they are seldom well treated; but if managed in a rational manner, and not over-watered when first separated from the parent plants, they are exceedingly beautiful. There are about 100 species in cultivation in this country, and many more are enumerated in catalogues. J. CROUCHER.

PLEIONES.

("INDIAN CROCUSES.")

FEW of our smaller growing Orchids are more beautiful than these little mountain gems when well-grown, and at this season of the year they form valuable decorative plants, besides affording a supply of choice cut flowers. All the species may be successfully cultivated in an ordinary plant stove, and this adaptability makes them even more welcome to our collections, and, as the price of these plants is now within the reach of everyone who has convenience for their treatment, they deserve to be more generally cultivated than at present. Well-established plants produce a good supply of off-sets, and by dividing the plants year after year, a good stock is readily obtained. They will be found to grow best in a compost of fibrous peat and chopped living *Sphagnum* Moss, to which sufficient coarse sand or grit has been added to keep the whole fresh and open. The pot or pan employed must be perfectly clean and well-drained, placing a layer of Moss over the crocks to prevent the compost from washing down. The pseudo-bulbs should be potted as soon after the flowering season is over as possible, and then placed on a shelf or stage near the light to make their growth. Do not water them too freely until the roots from the base of the young growth obtain firm hold of the compost, but, after this occurs, they may be watered more freely with advantage. A moderately cool and airy atmosphere suits them best during the summer, and repeated syringings are essential to keep them free from red spider and thrips, to which they are, unfortunately, rather liable. Every inducement must be given to enable them to make a vigorous growth during the spring and summer, for on this the free and profuse production of their delicate flowers depends. There are four species commonly met with in good collections, the first to open its blooms being *P. Wallichiana* or *P. precox*, as it is

sometimes called in allusion to this early-flowering habit. This is the largest-flowered species in the genus, bearing one or two flowers on a stem, of a rich lilac-purple colour delicately veined; the inside of the lip is yellowish, with about five rows of comb-like teeth running in longitudinal lines down the centre. This plant generally blooms early in October, and is closely followed by *P. lagenaria*, which has much smaller flowers of a similar lilac-purple tone, with delicately-veined segments, but the lip is very distinct, being richly blotched with carmine, and the rows of pectinate teeth being more fully developed. *P. maculata*, again, resembles the last in form, but is still smaller, with milk white sepals and petals, and a white, yellow, and carmine-blotched lip. This is one of the most delicate and beautiful of the whole group, and is rather rarer than the last-named. All the above species have purplish or brown bluntly-rounded pseudo-bulbs, covered with greenish warts; but there is yet another species with smooth tapering pseudo-bulbs of a dark green or purplish colour. This is *P. humilis*, the smallest of the whole group, and deservedly a favourite wherever it is grown. Its flowers are of the most delicate lilac, the margin of the lip being white, and as prettily fringed as the finest lace. The old pseudo-bulbs of this plant frequently throw off from twenty to thirty little bulbets, which fall on the fresh mossy compost, and soon form roots and plants. The latest introduction to this genus is *P. Reichenbachiana*, from Rangoon. The flowers are borne one or two on a short scape, the segments being rosy-lilac, and the lip tinged with faint purple and fringed with crimson in front. Popularly these delicate little plants are known as "Indian Crocuses," not a very appropriate name, yet they closely resemble in colour, habit, and time of flowering some of our hardy Croci. From a botanical point of view they may be regarded as a deciduous section of *Cologyne*, with which genus they agree in all essential characters. F. W. B.

LEAVES FOR HOT-BEDS AND LEAF MOULD.

THOUGH hot-water pipes have superseded the hot-bed generally, the annual leaf heap has not been dispensed with altogether, but still forms an important adjunct to the forcing department wherever leaves are procurable. In many a ducal and lordly establishment the Melons, Cucumbers, Rhubarb, Seakale, early Potatoes, and salads, not to speak of the hordes of bedding stuff, early forced flowers, and other things which go to supply the various departments, are produced in an out-of-the-way corner, where the rakings and sweepings of the avenues, walks, lawns, and other places are accumulated every year for the purpose of forming a fund of manure for universal use, in case other precarious sources, which generally afford the garden a supply, should fail. Decayed leaves, otherwise termed leaf mould, is a lost manure to all but the gardener, and he does not use at the most more than a fractional part of the available quantity on any estate. On waysides, behind edges and walls, in gullies and other places in the woods, the fallen leaves collect in tons every year, and are left to lie and rot, when, with very little labour, they might be collected and incorporated with the manure of the farm, or formed into compost heaps, to be afterwards employed as a rich and nourishing dressing to the land. Leaf-mould, either by itself or mixed with other soils, is eminently suited to the wants of most plants; for, though it is not a highly stimulating manure, it encourages root action in an extraordinary manner, and indirectly in this way promotes the growth of plants in a high degree, when, in some cases, more concentrated manures would, to a great extent, remain inert. To heavy soils, if assisted with lime, it can hardly be applied in too great a quantity for a time—but it is possible to overdo it, as has been the case in many kitchen gardens, where the original loamy staple has almost disappeared, under the continual application of leaf-mould or humus, rendering the soil quite unfit for the production of some crops. It is, however, chiefly with the utility of leaves for forming hot-beds that we have to deal, for it is after they have done duty in that way that they come in as a fertiliser. No other fermenting materials are so easily procurable as tree leaves, and none are so well adapted for making hot-beds; as when used in sufficient bulk they will afford a temperature sufficiently high for any purpose; and, while they never ferment violently, they retain their heat steadily for a longer period than any other material that can be employed, and this without turning or adding to, from January till December. Oak leaves are the best that can be used for hot-beds, and sometimes they can be procured alone in Oak plantations, but generally they are only procurable in a mixed state, and yet do very well. I may state that Beech leaves, which can frequently be collected by themselves, are about the worst that can be employed, either for hot-bed making or forming leaf mould. They are dry and hard, and do not ferment readily, and, when they come to be employed as a manure, the husks of the Beech mast generate Fungi in the soil worse than anything I am acquainted with. I have seen borders to which

the mould of Beech leaves had been added white with the mycelium of Fungi long after it had been applied. Hundred of tons of leaves are sometimes formed into hot-beds by building them up in a heap of a parallel or square form; but such a bed requires a good deal of time and labour to make, and it is needless adopting such a plan if there is a sheltered hollow conveniently near, or if a rough pit can be found, into which the leaves can be shot without trouble. Such a plan will also conserve the heat much better. At one large establishment I am acquainted with, an exhausted quarry is utilised in this way, and, when filled, the leaves afford a long-sustained store of heat, and a large surface for the accommodation of hand-lights and portable frames, in which large quantities of vegetables and other produce are turned out during the year. In autumn the spent leaves are carted out, when the estate horses are not otherwise employed, to the manure heap, and the quarry replenished again with newly-fallen leaves. Leaves for hot-beds should be collected as soon as they fall off the trees if we want to get the full benefit of their heating power, and in forming the bed they should be spread regularly and trodden. Leaves afford a steady temperature of from 90° to 100°, according to the depth of the bed, for nearly a whole year. For striking cuttings in, nothing excels such a bed. Melons also will grow and fruit well in such quarters till November; and Cucumbers for nine months in the year, with the assistance of linings in spring and autumn. In many large gardens, in fact, no other conveniences exist for cultivating such crops. Bottom-heat from leaves or fermenting materials generally, when steady and not too violent, is of a far more healthy nature than that afforded by hot-water pipes; hence many cultivators, who employ pipes by preference for top-heat, still retain the leaves for bottom-heat in Pine pits and other such places. The advantages of the hot-water system are convenience and cleanliness; but with beds formed entirely of leaves—Oak if possible—the trouble of renewing occurs only once a year if the bed is deep enough. I believe in most of the extensive Pineries at the Royal Gardens, Frogmore, the hot-beds are still formed of Oak leaves, and the Pines there have always been celebrated for their great weight and excellence; only lately we hear of fruits from those Pineries weighing close on 10 pounds apiece, grown in this way. The cloche, which is becoming more common in this country than formerly for the culture of early salads and seeds, should be supplemented with a leaf-bed, say about 2 feet or 18 inches thick; for a very gentle heat is sufficient for such things, and a moderate quantity of leaves would form a bed of sufficient breadth to accommodate as many cloches or hand-lights as would be needed in a very large establishment. J. S. W.

SELAGINELLAS.

To the descriptive list of Selaginellas given in THE GARDEN, Vol. IV., p. 353, allow me to add the following:—For carpet beds or borders nothing is better than *S. Kraussiana* or some of the variable forms of *S. Martensii*, which grow freely, are of a dense habit, and always present a fresh and cheerful appearance. I have seen these plants used with good effect for covering bare walls in plant stoves, by fixing galvanised wire netting an inch and two from the wall, and filling the intervening space with peat and Sphagnum, into which rooted pieces of Selaginella were planted and syringed daily until fairly established.

Such a wall, however, is always more troublesome than one covered with *Ficus repens*, or its smaller variety *F. minima*. Some of the Selaginellas make fine specimens when on cones or cylinders formed of peat and chopped Sphagnum Moss; for the generality of species, however, the flat pans generally used should be employed. The following species may all be seen in the large Fern-house at Kew.

S. Galeotti.—This is a loose rambling species, of a deep green tint, but, being distinct, it is well worth growing, and under good culture it makes a nice plant. It is a native of Mexico. In some gardens it is grown under the name of *S. Schottii*.

S. patula.—This is a dwarf creeping species, of a light but bright green colour, and one that grows well in a flat pan, in which it forms a dense mass. It does not appear to be so generally distributed in gardens as it deserves to be.

S. hæmatodes.—This very effective caulescent species grows from 12 to 18 inches in height, and forms large branched triangular fronds nearly a foot across, and is of the freshest green colour imaginable. It somewhat resembles *S. erythropus*, but is in every way larger and less spreading in habit. When well grown it is fully equal to any Fern as regards decorative purposes, and one would be tempted to cut its fresh green fronds for arranging along with cut flowers, only that it and nearly all other Selaginellas so soon curl up after being cut unless laid flat on Sphagnum Moss, wet sand, or other moist material.

S. inæqualifolia.—This is a robust caulescent or erect-growing plant, often 2 feet or more in height. Its broad growth is of a fresh green colour; and, although the plant is apt to produce a large proportion of fertile branches or spikelets, which detract somewhat from its ornamental appearance, still it deserves a place in every collection.

S. fulcrata (africana).—This, one of the best of all the caulescent species, produces dense masses of broad feathery fronds, which, in well-grown specimens, are often 12 to 16 inches in height, and of a fresh green colour, with red or purplish stems. It is a native of Western Africa.

S. viticulosa.—This is a pleasing creeping or succulent species, with a light feathery appearance, quite different from many of the others. It makes a nice specimen grown in a flat pan, and is well deserving of culture. It is a native of Columbia, and succeeds well in a moderate temperature.

S. ascendens.—A compact creeping or sub-erect species, with branches arranged in a divaricate manner. It is of a deep rich green colour, lighter at the apices

of the branches than elsewhere; when well grown it makes a very effective decorative plant.

S. Griffithii.—This is an elegant creeping species, the tips of the fronds of which are gracefully recurved. It is distinct in appearance, but requires a warm and moist atmosphere to grow it successfully. It is a native of Borneo.

S. Wallichii.—This is one of the most robust plants in the whole group, producing great branching fronds from 2 to 3 feet in length. It is caulescent and of a deep shining green colour, the tips of the branches each bearing slender pale green spikelets. When liberally treated this makes a noble specimen. It is a native of Pëbang and the Indian Archipelago.

S. denticulata.—This plant is not known or grown in gardens so much as it deserves to be. It may now be seen on the borders of the walk leading to the rockery at Kew, where it forms bright patches of the most vivid green, and creeps close to the moist earth or mossy

The Tree Selaginella (*S. cresia arborea*).

stones. It may, possibly, prove hardy in sheltered positions, and, if so, it will prove a favourite wherever it is grown.

S. pilifera.—This pretty plant belongs to the renatale section. Its fronds all radiate from the centre in a circle, and are of a fresh pale green. When carefully cultivated it is one of the most pleasing members of the whole group, but it is rare in collections.

S. cæsia arborea.—This plant, of which we give an illustration, grows well planted out in a moderately cool Fernery. We have seen it drooping 10 or 12 feet from Tree-Fern trunks. B.

WINTER FORCING THE LILY OF THE VALLEY.

WITHIN the past three years (says Mr. Peter Henderson, in the *American Agriculturist*), the demand for the flowers of Lily of the Valley has increased to such an extent, that though the importation of roots has probably trebled each year, the price of the flower is still quite as high as when the forcing first began. The price last season, from December to May, averaged 10 dollars per 100 sprays at wholesale—a price which, when the bulk or weight of the flower is considered, is something wonderful, and probably higher in proportion to the bulk than that of any other flowers, unless it may be those of some species of Orchids. The high price of the flowers is due to the fact that the success of the crop is not always certain. The failures which attend it are mainly owing to the use of improperly developed roots. As with other similar plants, a certain size or development of the crown, or underground bud, is essential to produce the flower. What that size should be, is not, even with the most experienced, always easy to determine. In the Tuberose, for instance, the Japan, and some other Lilies, we find that bulbs that are less than an inch in diameter are not certain to flower. These rules, however, as to size and shape are not given as certain, for hardly any of us have had experience enough to say with accuracy at what size the crown of the Lily of the Valley, or the bulb of a Tuberose or Lily will not flower, although we may say with considerable certainty, if the crown is large, that it will do so. It is the want of this knowledge that, in my opinion, has made the forcing of the Lily of the Valley so uncertain; thousands of roots have been imported that have not given flowers sufficient to pay the first cost of the roots. The cost is about 25 dollars per 1,000 for single crowns; and, as each produces but one flower-cluster, it will be seen that nearly all should flower to make the business of forcing fairly profitable, even at 10 dollars per 100. We last year imported what seemed a very fine lot, which, on coming into flower, showed that one-third were "blind," or flowerless. As in forcing the Hyacinth, and other similar bulbs, crowns of the Lily of the Valley should be covered up outside for a few weeks before being brought into the greenhouse to force. Those we flowered last year were imported about the middle of November, and were then packed closely together in light rich soil, in boxes 3 inches deep. These were covered up outside with hay until the 1st of January; they were then brought into a greenhouse, facing the north, where there is no direct sunlight at that season. The temperature was kept at about 70°, with a moist atmosphere, and by the 1st of February they were in full flower. The Lily of the Valley could be grown finely in a Wardian case, as it would there get the proper light, with the necessary damp atmosphere. When grown in greenhouses exposed to sunlight, it is necessary to shade the glass very heavily. When the flowers are about to open, they should then have light to give the leaves a healthy green colour.

WINTER-FLOWERING ODONTOGLOSSUMS.

ODONTOGLOSSUMS are favourites with most Orchid-growers, as they may be grown without any great expense either of fuel or labour. They are, indeed, in every sense of the word, "cool Orchids," and the best kind of erection in which to cultivate them is a low span-roof house, some 8 feet high in the centre, with side walls about 5 feet. The breadth of the house may be 12 feet; this gives 4 feet for the side benches or tables, and 4 feet for the path. Provision must be made for thorough ventilation, covering the openings with perforated zinc or wire gauze so as to exclude cold currents of air or draughts. A house of these dimensions, and 10 to 50 feet in length, may be heated sufficiently for Odontoglossums by a flow and return pipe passing round it under the side-benches. Or, in other words, a house in which these plants may be grown perfectly, requires no more piping than is considered necessary for heating an ordinary greenhouse. The benches should be of slate, on supports of either iron or wood, the former being preferable on the score of durability. These benches should be covered either with Derbyshire spar or Cannel-coal broken up into small nodules, upon which the pots should be arranged. Cannel-coal always appears clean, and its dull black colour is not at all conspicuous, while it efficiently answers every purpose for which spar or shells are used. Most Odontoglossums grow

freely in a compost of fibrous peat, some dried horse-droppings, chopped Sphagnum Moss, and sand. The pots should be thoroughly clean and dry, and plenty of drainage should be used, in order that all superfluous moisture may pass away readily. They require an abundant supply of moisture when in a healthy growing condition; but, like other plants, they are injured by stagnant water at the root. The following species are the most worthy of cultivation for their winter-flowering qualities.

O. Alexandræ.—This is one of the most beautiful species in the genus, and deservedly popular with Orchid-growers. Its flowers vary from pure white to white suffused with rosy-lilac; they are heavily blotched on the lip and sepals with brown. A remarkably fine specimen of this species at Meadowbank bore, some time ago, 120 flowers, 56 of which were on one spike; and I saw many plants of this species growing in a brick pit at Meadowbank last summer, in very fine condition. This species should be grown by the dozen where there is convenience, as, where a good stock is kept, it may be had in bloom throughout the year with but little intermission. Its flowers last a long time in beauty. After potting, this and all other Odontoglossums should be surfaced with a layer of fresh green Sphagnum, which conceals the compost, gives the pot-tops a clean and fresh appearance, and maintains an equable state of moisture at the root.

O. cristatum.—This is not so showy as some species; but it is, nevertheless, highly interesting, and well worth cultivating. Its flower-spikes are slender, often branched; and the flowers yellowish, heavily blotched with purplish-brown. The crest of the lip is white, and in some varieties a large proportion of the lip is also white. It flowers freely during the winter, and lasts a month or six weeks in perfection.

O. Cervantesii.—A very pretty dwarf species, introduced from Western Mexico in 1815, and often known in gardens as *O. membranaceum*. It has small, angular, one-leaved, pseudo-bulbs, and produces a flower-spike from 4 to 6 inches long, bearing four or five delicate membranaceous flowers, more or less, of a soft rosy colour. The bases of the floral segments are marked with transverse bars of brown or brownish-crimson, the lip is white. It is a pretty little species, well worth growing, and lasts from three to four weeks in flower.

O. cordatum.—A distinct species, found in Mexico and Guatemala, and introduced to this country about 1837. In bulbs and foliage it somewhat resembles *O. maculatum*, but is very distinct from that species. When well established it bears numerous erect spikes of flowers, the sepals and petals of which are about 1½ inches long, lanceolate, the apices being attenuate, and often wavy. In colour they are very remarkable, being heavily blotched with a dark brown (in some varieties of peculiar richness) on a ground colour of pale greenish-yellow. The lip is heart-shaped, of a white colour, blotched, and often margined with brown, and furnished with a pubescent bi-lobed crest.

O. roseum.—This species flowers very profusely during winter and spring, lasting from three to four weeks in perfection.

O. grande.—Though an old, this is a truly magnificent species, which blooms during the autumn and winter months. This, *O. Inseayi*, *O. citrosum*, *O. Krameri*, and *O. Phalenopsis*, like a few degrees more heat than the generality of Odontoglossums, and will be found to succeed better in a Cattleya-house or in an intermediate temperature rather than in the cool house. *O. Phalenopsis* is especially sensitive to either extremes of temperature, or to stagnant moisture. Well-established plants of *O. grande* make fine subjects for exhibition, and produce very large flowers of golden-yellow, heavily blotched and barred, which are in great profusion when the plant is well grown. No other Odontoglossum is so effective as this; and it has the good quality of retaining its gorgeous beauty for a considerable period.

O. luteo-purpureum.—Of this we have in cultivation several forms, which are frequently sold and named *O. radiatum* or *O. Hallii*. It is a fine plant, and good specimens of it bear from twenty to thirty flowers on a spike 4 or 5 feet long. A fine specimen of the variety called *Hallii* flowered at Fernhurst, and produced thirty flowers, some of them 3½ inches across, on a branched spike nearly 5 feet long. Three smaller spikes were borne by the plant at the same time. The sepals and petals vary greatly in breadth in different forms, and are of a yellow colour heavily blotched with brown. The lip is broad, with a white fimbriate margin, the disc being blotched with brownish-crimson; some varieties of this plant are richly coloured.

O. Inseayi.—This is another fine winter-flowering species from Mexico, somewhat resembling *O. grande* in habit. It is a very free-flowering species, the sepals and petals of which are yellow, barred with brown. The lip is of the richest golden-yellow, often spotted with crimson. It flowers all through the dull season of the year, and lasts in beauty from three weeks to a month.

O. Pescatorei.—This lovely species, like its congener *O. Alexandræ*, blooms at different times during the season. I have

recently seen it in great beauty in several places, and its pearly blossoms are doubly valuable at this dull period of the year. There are several varieties of it, some nearly white, others spotted and blotched with dense purple, but all beautiful. I measured a flower of it the other day in Lord Londesborough's fine collection at Sarrilton, and found it to be fully 3 inches across. This is one of the finest varieties I have seen, its sepals and petals being very broad, and of good substance and colour. This plant roots vigorously in the compost above-named, and grows well in the cool house. It was introduced from New Granada about 1851, and is one of the finest species in this beautiful genus. It flowers from three to five weeks.

O. pulchellum.—This pretty little white-flowered species from Mexico, was introduced some time before 1841. There are several varieties of it, some bearing flower-spikes very little larger than those of the Lily of the Valley, while others bear flowers an inch in diameter. The sepals and petals are of a pure crystalline white. The lip is bent nearly at right angles, and has a crest shaped like a **W**, of a golden or lemon-yellow colour, spotted with crimson. The flowers are borne nine or ten together on erect spikes, among dark, grass-like leaves. It is a profuse bloomer when thoroughly established, and its fragrant flowers form a very elegant addition to bouquets. It lasts a month or even six weeks in perfection.

O. Rossii.—This, like *O. Cervantesii*, is a very dwarf species. Still, one variety of it, named *spurbum*, bears very fine flowers; its blossoms appear, two or three together, on a spike 5 or 6 inches long. The sepals are of a creamy white colour, spotted or blotched with purplish-brown; the petals, broad, pure white, barred transversely with purple; the lip, pure white, with a golden crest. This pretty little species should be in every collection. It flowers about this time of the year, or a little earlier, and lasts about a month in flower.

O. triumphans.—This is a very rare plant, and, at the same time, one of great beauty. It may be considered the best of the yellow-flowered section, if we except *O. grande*. Its flowers are from 3 to 4 inches across, and are borne on a nodding spike. The sepals and petals are of the richest golden-yellow, blotched with brown. The lip is white, with a golden crest, and the apex tipped with rosy-purple. This valuable plant blooms at different seasons, but generally during the winter and spring. In habit, it somewhat resembles that of *O. Pescatorei*, and the bulbs are sometimes spotted with brown, as in that species.

O. Uro-Skinneri.—This has large speckled pseudo-bulbs and broad foliage, and is altogether distinct from most of the other species, both in habit and flower. Like most other Orchids, it varies considerably in the size and colour of its flowers, some varieties being very richly tinted. The sepals and petals are yellowish-green, more or less heavily blotched with purple-brown. The lip is broadish, cordate, of a white colour mottled with rose. This species grows well in the coolest house, but requires an abundant supply of moisture nearly all the year. It bears from ten to twenty flowers on spikes from 2 to 3 feet long, when well established and in good health.

O. Bictonense.—This is another species from Guatemala; and one which bears numerous erect spikes during the winter and spring months. These spikes are from 18 inches to nearly 3 feet high on good specimens, and bear fifteen to twenty flowers, which open in gradual succession. The flowers measure about 1 inch across, and are of a yellow colour blotched with brown. The lip is often white, and sometimes of the deepest rose. It sports into several varieties, the best of which are very ornamental.—*The Gardener*.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Celosia pyramidalis.—I see you allude (see p. 330) to my plants of this *Celosia*, of which I have had samples over 4 feet in height and 2 feet 8 inches in diameter, grown in 8-inch pots. The way in which I grow them is as follows:—I sow the seed in a pan in a hot-bed in March, and when the young plants are large enough I pot them off into thumb pots and shift according to size. The soil which I use is leaf mould and loam, a little charcoal, and sand. I water copiously, and occasionally with liquid manure, and the result is most satisfactory.—**CHARLES FRISBY, Blankney.**

Vanda cœrulea.—This charming *Vanda* is now gorgeously in bloom here, each spike bearing, on an average, from ten to twenty blossoms, the sepals and petals of which are delicate azure blue. This fine *Vanda* is considered by some to be a more difficult plant to cultivate than *V. tricolor*, *V. sœavis*, or *V. gigantea*; but here it thrives perfectly treated as these are, and is certainly a more profuse flowerer than any of them. Like its associates, it is growing in an oak-wood basket or crate entirely filled with healthy Sphagnum, which is elevated so as to form a pyramid.—**J. MERR, Clonsford.**

Propagation of Cyanophyllum.—Can the top of a *Cyanophyllum* be propagated on the old plant, as in the case of a *Dracœna*, by removing a ring of bark and placing moist Sphagnum Moss around the incision?—**T. M.** [You might possibly succeed in striking *Cyanophyllums* in the manner just alluded to, but a better and quicker plan would be to cut off the top and treat it as an ordinary cutting, by inserting it in a pot of sandy earth and plunging it in a genial bottom-heat, under a close case or shade. Sufficient humidity must be kept up to prevent the foliage from shrivelling, and then success is reduced almost to a certainty.—**B.**]

THE GARDEN IN THE HOUSE.

POT PLANTS IN ROOMS.

Few floral ornaments look prettier in sitting-rooms than well-grown pot plants, which have a great advantage over cut flowers, inasmuch as they last longer in perfection. To townspeople, who have no gardens or glass houses they are a real boon. Plants of all kinds, suitable for rooms, may be obtained in Covent Garden Market, but being, as a rule, reared tenderly in heat, when placed in their new quarters they soon drop their blossoms. Avoid, therefore, plants brought direct to the market from a stove or other house much heated, and select such as have been brought up hardily, for no care will keep plants just out of a lothouse fresh or healthy looking; the sudden change from heat to cold is certain to make them flag. Having made sure that the right sorts of plants have been obtained, the next thing to be considered is, how the pots are to be concealed, as common garden-pots are anything but ornamental. To remedy this evil, some set their pots in paper covers of different colours; others slip them into china pots. Rustic covers are also sold for hiding pots while some conceal them in the following manner:—A bundle of common Brake Fern is obtained, and the ends of the Fern fronds cut in a slanting direction with a sharp knife, are inserted in the soil with which the pot is filled, close to the rim, over which they are broken, so as to make them droop and hide the pot. For those who may not like this plan, and who will not go to the expense of china pots, a new improvement on the plain rustic expanding covers has lately been introduced, differing only from the old style in being ornamented with artificial Ivy, Vine, and other varieties of leaves which tend to give it a pretty appearance. Such pot-covers are well suited for plants in halls, or for ordinary use; but, for the dining-room and dinner-table, they should be of china, than which nothing is more effective. Some are made to stand on a table or bracket, painted in pairs to match; while others are mounted singly, on tripods of iron or wood. I have seen a design made of bronze to stand on a table; at its base were two china pots, and raised about a foot or 18 inches, supported on a pillar of ornamental bronze, was another china pot. Being of bronze this stand was probably intended for the hall or dining-room, as I also saw several in ormolu, which would look lighter for drawing-room decoration. After plants have been placed in such ornamental pots or covers, the surface of the soil in which they are growing should be covered either with silver sand or Wood Moss; if, with the latter, and any of the plants happen to be Ferns, care should be taken that the Moss does not cover any of the young fronds. All plants should be removed to the conservatory at night, if there is one; if not, into some room in which no gas has been burning. It is bad enough to keep plants in a gas-lighted room for any length of time, but, after the gas is turned out, they should be removed, as the atmosphere being still charged with its fumes sadly injures them. In the morning water should be given them if they require it. Palms and other fine foliaged plants should have their leaves sponged over with water every morning, and the flowers of *Pelargoniums* and similar plants may be made to last for a long time, if a drop of gum, such as is used for cut flowers, is dropped into the centre of each bloom. By observing these little items, plants may be kept in good health just double the time they otherwise would be. Plants look well set on brackets, though this style of decoration is not often resorted to; I am certain, however, that if tried, a good effect would be the result. Brackets may be purchased made of different materials; some consist of terra cotta, others of china; some are made of wrought iron, painted to imitate bronze, others consist of Swiss carved wood, and others are gilded. Some brackets are fixed flat against the wall, others are made to fit into corners. Those made with a hollow, into which the pot can be dropped out of sight, are much the best for upright-growing plants; but where an Ivy-leaved *Pelargonium*, or any drooping plant, is employed, it does not matter, as the foliage of the plant, if a good specimen, quite conceals the pot from view. One of the most effective plants for this style of decoration is a large and handsome specimen of *Asplenium flabellifolium* (Fan-leaved Spleenwort). No one who has not seen a plant of this so placed can have any idea of its beauty.

A. HASSARD.

LAST BOUQUET OF THE SEASON.

OCT. 6.—*Mrs. Ruralist* has just brought me a bouquet for my library table, and says "I think this will be the last bouquet of this season cut from the garden, as the air is chilly, and we shall probably have a frost to-night." We have already escaped two weeks beyond the usual time of our first frost, still this notice of the "last bouquet" from the garden is not welcome tidings, even though expected, and long delayed. As I look upon the bouquet before me, which is composed of Tuberoses, scarlet Sage, and rose Geranium leaves, I am

reminded of something which I read a year or two ago about "flowers on the table," mingling the importance of making the table at meal time look pleasant and inviting every day, instead of occasionally, when there happens to be company about. I do not recollect the exact arguments used by the writer referred to, but remember they were forcible and well put, and it is to be hoped many a housewife has heeded the advice given. I know of at least one who would as soon forget the more important dishes of a meal as the one or two bouquets of flowers which always mingle their fragrance with those coming from the staffs of life. Of course it is not to be supposed that every family can have a conservatory to supply the table with bouquets of fresh flowers during the winter, but the woods and fields furnish abundant materials if nothing of the kind has been produced in the garden, and a cluster of red berries with autumn leaves intermingled; even the Ferns, Mosses and twigs of evergreens may be employed for this purpose, and if tastefully arranged cannot fail to be effective. A few sprays of dried Grass, with the scarlet berries of Holly, Black Alder, and others, may be employed for making bouquets. It matters not what the materials are if the best of those at command are selected and arranged with taste. But it must not be forgotten that this "taste" comes with practice and association, and the mother who never attempts or tries her hand at such devices must not expect to become skilled in the act, or see her daughters grow up accomplished housewives. The "last bouquet" may be taken from the garden this month in many a northern locality, but its place should not remain empty for an hour or day; because it is these little things which when put together make up the sum total of life's pleasures.—*Moore's Rural*.

Delicate Drooping Plants for Vases.—On going through the stoves of one of our metropolitan nurseries, the other day, I noticed two kinds of delicately-formed bright green plants, hanging from the Moss of the Orchid-baskets to a length of about 18 inches. Closer inspection proved them to be the wild English plants, *Galium palustre* and *Oxalis corniculata*. Either the roots or the seeds had been overlooked while cleaning the Sphagnum in which the Orchids were planted; and hence this elegant graceful drooping fringe to the square lattice-work baskets. I need hardly say that their relatives, in their native bog, might be excused for not recognising them, since they were considerably attenuated by the unnatural heat to which they were subjected; a gardener might call them "drawn," and a wireworker "fine-drawn." They are, however, so pretty for vases with delicate stems, that I shall certainly try to grow them in a warm greenhouse in pots of Sphagnum standing in saucers, and hung from the roofs.—*W. T. P.*

A New Medicinal Plant.—In a pretty Alpine shrub, well-known in the Chilian Andes, but not, as yet, cultivated in Europe, remarkable medicinal qualities have been recently discovered, in a curiously accidental manner. A small flock of mountain sheep, suffering from a peculiar form of liver disease, was recently driven into a separate enclosure high up in the mountains, to keep them separate from other flocks. There they were left to perish or improve, as it might turn out. To the surprise of the proprietor they all rapidly improved, and were eventually found to be perfectly cured. What could have produced the unexpected change, and caused appetite and strength to return in such a marvellous manner? It certainly could not be the extremely scanty mountain Grass. Being watched, it was found that they left the ordinary herbage untouched to browse upon the leaves and young shoots of a shrub, of which the fence was formed. This shrub was the *Boldoa fragrans*, commonly known as Boldu, the original Indian name. Its foliage is brilliantly green, and the flowers, which are pale yellow, are bright and effective. The flowers, leaves, or bark, when crushed, emit a strong and fragrantly aromatic odour, from which the plant has received its specific name. An essential oil is also expressed from them, which is known as boldine. The experimentalists say that it contains an alkaloid that promotes healthy digestion, and acts directly upon the liver, like calomel, but without any of the bad results which over-doses of calomel induce. The French physicians who have experimented on the action of boldine, and its value as a medicine, may be over sanguine, but they expect the most valuable results from its introduction to the European pharmacopias. *Boldoa fragrans* has opposite, ovate, short-stalked leaves, and the flowers appear in little axillary racemes, the male and female flowers being on different plants. It bears a fruit about the size of our common Hawthorn, which is of pleasant flavour, and often eaten by the mountaineers. The bark is used by tanners, and the wood is preferred to any other for charcoal, possibly on account of the slight aromatic fragrance which it sometimes emits in burning.

VARIETIES OF THE BANANA.

THE *Florida Agriculturist* contains the following remarks upon the treatment of this fruit and the characteristics of its varieties, which may interest growers of tropical fruits. There are several varieties of Banana cultivated in the Island of Jamaica. Of these the Martinique as named there, but called here the Jamaica, is considered the best, as being hardier in growth, easier to cultivate, not easily blown or broken down, and the best for eating. They bear within one year after planting, and the bunches are very large. We have seen some that a man could not lift. The fruit is long, and of a rich yellow colour. They are often brought here from Nassau. Once planted they require no care, but will continue growing, suckering out, and bearing. All other sorts of Bananas have been cast aside since these were introduced into the island. Another long Banana, called the Tiger, from the skin of the fruit being striped with black, is grown in some places, but the fruit is not considered so good as that of the above-named sort. The Otahite is another of the same class as the long Bananas. The fruit must be very ripe before it is fit to eat. The flesh is of a rich strawberry colour. This is, however, not a profitable kind to grow. Of short Bananas, the Dwarf or Chinese is a kind not growing more than 4 or 5 feet high, with a strong, stout body. It bears large bunches of fruit, which hang nearly to the ground, and stand firm, but the fruit is of no account, and is usually used as a culinary vegetable, like a Plantain. The Redskin is a strong-growing plant, which bears large bunches of handsome fruit; but in Jamaica it is not considered equal to the Martinique. A kind called the Apple is not a profitable Banana to grow. The bunches are medium-sized, and the fruit about the length of a person's finger, and very delicious; but the plants root up easily, and they require more cultivating than other kinds. Finally, the triangular Banana is the worst of all the Bananas. Its bunches are medium-sized; but the fruit is not nice, being slimy. It should be baked before eating. There are other varieties grown; but these are the only kinds that are commonly met with in the West Indies. Every negro hut has Bananas growing around it. They are manured with ashes from the kitchen. As the bunches become fit to use, they are cut off and taken into the house to ripen; for Bananas that ripen on the stalks are not near so nice as those cut, as they contain a strong alkaline juice which exudes from the stalk when cut off. The fruit should be allowed to fill out and be fully grown; the bunches should be then cut off and hung upside down to ripen in the house. The green fruit can be used as a culinary vegetable, by having the skin peeled off before boiling, and mashed up with butter or lard, with pepper sprinkled over it. A favourite way in the West Indies is to boil Bananas with salt beef or pork, and to mash them up with some of the fat skimmed off the water. When ripe, the fruit can be made into pies, similar to Apple pies, by peeling them, placing them in a dish, and pouring in butter and sugar that has been rubbed together over them before baking. Bananas are delicious done in this manner. The Banana will not stand frost, the leaves being so thin that they are susceptible to any extreme; but some of the species may be hardier than others. In the West Indies, when the stalk comes up spindling and weak, it is cut off just below the leaves. This does not kill it, but has a beneficial effect in making it thicken out, and become stronger. We think that if this plan were adopted with those that had been affected by frost it might have the same tendency, but it should not be done until cold weather had entirely passed away and the plants show an inclination to grow. As the bunches are cut the stalks should be lopped down to within a foot of the ground, cut into pieces and placed around the roots: the same with the leaves. When plants with young fruit are caught by frost before coming to perfection, we think it is the best plan to cut down the whole stalk at once. This enables plants left standing to receive full nourishment on the return of spring. In the West Indies, if the Banana is highly manured, the stalk or body, as it is called there, will grow very large and succulent, but at the expense of fruit. Ashes have been found to be the best manure that can be given, with an occasional sprinkling of salt.

The Cost of Water-squirting.—On the recommendation of the Parks, Commons, and Open Spaces Committee of the Metropolitan Board of Works, that "the fountain in Leicester Square be closed until the 1st of May next," it was stated at a recent meeting that the water bill for supplying the fountain for three months, when it was playing for six hours a day, was £250, and that to work it for four hours per diem per annum would be £1,000. It was decided to close the fountain until the time recommended. Here is another proof of the advantages of allowing fountain builders their own way in a garden. The fountains in Leicester Square are the most peurile imaginable, yet the cost of the water alone amounts to a sum that would suffice for the support and keeping up of a large and beautiful garden.

THE PUBLIC PROMENADE AND GARDEN OF RIO JANEIRO.

THE magnificent bay of Guanabara, along the shores of which the public Passeio stretches for a considerable distance, has been celebrated for its beauty ever since the first settlement of the Portuguese in the Brazils. At a time when unadorned by Art, or any plantations beyond those sown by lavish Nature, in a delicious climate, that beach was called "the walk of the lovely nights;" and, no doubt, in the exquisite evenings and nights of that beautiful region—the placid sea rippling gently to the beach, and brilliantly lighted by the tropic moon—that the name was an appropriate one. Villeganon, as early as 1555, wrote enthusiastically of the bay of Guanabara, and declared that nothing but the Bosphorus could be com-

as that now occupied by the public gardens, was low, marshy, and unhealthy; causing difficulties which it required all the energy of such a skilful administrator as Vasconcellos to overcome. But, by dint of perseverance and a lavish outlay, the gardens and grand sea-walk, which are now the admiration of all travellers, were successfully created and richly embellished and planted. The plantations inaugurated by the garden-loving Viceroy are now nearly a century old, and are flourishing in all the luxuriance and magnificence of mature growth. The great Mangoes (*Mangifera indica*) form the salient features among the larger trees; and among the shrubs and undergrowths, of many beautiful and exceedingly various kinds, the Rose-Laurel (*Nerium Oleander*), so beautiful and luxuriant in warm climates, is there seen to the greatest advantage.

View in the Public Promenade, Rio Janeiro.

pared to it for beauty. He described also, in verses that sometimes verge on the extravagant in their magniloquence, the beauties of the gardens of Rio; but these are now but archaeological matters, for everything has changed at Rio since the days of the poetical traveller. The introduction of the trees and plants of other climates, which nearly all thrive luxuriantly, has changed the entire aspect of the surrounding country, and enriched the vast plains with various kinds of foliage, which have become as important and as beautiful features in the landscape as the native vegetation of that region, in which wood was somewhat deficient.

It was not until the year 1778, during the government of the fourth Viceroy, Luis de Vasconcellos, that the present public promenade was created. A great part of the ground now occupied by the promenade when thus projected, as well

The region of Entre-Rios has many other noble gardens to boast of. All kinds of European fruit trees flourish vigorously; especially the Peach, though it requires renewing every fifteen or sixteen years. The Pear and the Apricot have also acclimated themselves in an extraordinary manner, notwithstanding that they are so essentially natives of temperate and even cold climates. Among the best known gardens in the neighbourhood of Rio is that of General Urquiza, which may be taken as a model of the best Brazilian gardens; all of which have, however, as it must be confessed, more the aspect of vast nurseries than of gardens, in the European sense of the word. They possess, however, with their long shady alleys, their general aspect of vegetable luxuriance, the soft air that gently stirs the luxuriant foliage, which simply to breathe is a pleasure, a charm peculiarly their own;

and, with perseverance and a little stronger infusion of European art, marvellously beautiful effects will, doubtless, be achieved in and about Rio at no very distant period, of a kind of which the most advanced horticulturists can at present form no definite idea; especially as nearly all the plants of other tropical countries, as well as those of temperate and even cold climates, appear to thrive in that favoured region quite as luxuriantly as does the native vegetation.

H. N. H.

THE HOUSEHOLD.

RECIPES.

To Preserve Pears.—Parboil some Pears with the peel on, take them out of the water, peel and quarter them, then let them lie twenty-four hours in large dishes, with powdered lump sugar thickly sprinkled over them; to 6 lbs. of Pears put the same quantity of loaf sugar, 1 oz. of ginger sliced thin, the peel of three Lemons cut into thin strips, and one pennyworth of cochineal. Stew gently for five hours, and keep in close covered jars.

Apple Jelly.—Soak 1 oz. of gelatine in a pint of cold water for two hours; turn it into a stewpan with half the rind of a Lemon thinly pared and cut into strips, and $\frac{1}{2}$ lb. of loaf sugar. Stir this mixture over the fire until the gelatine and sugar are dissolved, add 1 lb. of good cooking Apples, pared and cut into thin quarters. Let these all simmer until the Apples are quite tender and the syrup clear; but the jelly must not be boiled fast or it will be a failure. Pour it into a mould in which cold water has been standing. Let it remain until the next day, and then turn it out, and place whipped cream, sweetened and flavoured with lemon juice, round it.

Preserved Seville Oranges.—Take any number, and rather more than their weight in white sugar. Slightly grate them, and score them round and round with a knife, but not very deeply; then put them into cold water for three days, changing the water two or three times a day. Tie them up in a cloth, and boil them till they are soft enough for the head of a pin to penetrate; while they are boiling put the sugar on the fire, with rather more than half-a-pint of water to each pound; let it boil for a minute or two, then strain through muslin. Place the Oranges into the syrup till it jellies and is of a yellow colour. Try the syrup by putting some to cool; it must not be too stiff. The syrup need not cover the Oranges, but they must be turned, so that each part gets thoroughly done.

Quince Marmalade.—Peel the Quinces, quarter them, and remove the cores and pips. The quarters should be thrown into a pan of cold spring water as they are cut, to preserve the colour. The Quinces should then be put into a covered jar with one quart of water to 1 lb. of fruit, and stewed in a slow oven for several hours till they are quite tender, and of a bright red colour. When they are thus prepared for marmalade, weigh them, and to every pound of fruit allow $\frac{1}{2}$ lb. of crushed lump sugar. Put the fruit into a preserving pan, and bring it gently to a boil, stirring frequently all the time. Continue boiling till the whole is quite soft and a smooth pulp; then add the sugar, and again bring the fruit to a boil. Continue boiling gently for twenty or twenty-five minutes. Take the pan from the fire, and paste down the marmalade in jars while hot with double papers, care being taken to have the paste quite boiling, and to strain the papers tightly over the jars.

—Take 4 lbs. of Quinces pared them and quartered, lay in a stone pan with a teacupful of cold water and a little pounded loaf sugar ($\frac{1}{2}$ lb.), cover the jar closely and let it remain on a stove in a cool oven until the fruit becomes red and tender. Have ready a syrup made of $3\frac{1}{2}$ lbs. of loaf sugar, boiled with a pint and a half of water for ten minutes. Add to this 1 quart of Quince juice, prepared by stewing 1 or 5 lbs. of Quinces in the same manner as before described, and straining their juice through a coarse cloth. Place in a preserving pan the syrup, fruit juice, and the 1 lbs of Quinces, let them boil until the marmalade is tolerably stiff, carefully stirring it all the time.

Walnut Ketchup.—Boil or simmer a gallon of the expressed juice of the Walnuts, when they are tender, and skim it well; then put in 2 lb. of anchovies, bones and liquor, the same of Shalots, 1 oz. of Cloves, ditto of Mace, ditto of pepper, and one clove of Garlic. Let all simmer till the Shalots sink; then put the liquor into a pan till cold, bottle, and share the spice with each. Cork closely, and tie a bladder over it. It will keep twenty years, and is not good till after the first. Be very careful to express the juice at home, for it is rarely made but ruined if bought.

—Perhaps there is no better Walnut ketchup than the liquor from pickled Walnuts. Walnuts rob the vinegar of its acid very completely, and then suffer for want of the keeping property which they have consumed, whereas ketchup is the better for not being too acid. Take out the old vinegar and bottle it for ketchup, and put

fresh vinegar to the Walnuts, and two good ends are gained. The next best is: put Walnuts into a stone jar, cover them with very strong vinegar, and let them stand for six months or a year, but look at them now and then, and fill up with vinegar when necessary. Then take out the liquor, and to every quart put a clove of Garlic, two ounces of anchovies, half-a-pint of red wine, a little salt, and mace, cloves, allspice, long pepper, and black pepper, of each a $\frac{1}{2}$ oz. Boil altogether until the ketchup has the full flavour of the spice, let it get cold and bottle it. Another way is to grind the green Walnuts in a mill, or pound them in a mortar, and squeeze out the juice through a coarse cloth. To every gallon of juice put 1 lb. of anchovies, 1 lb. of bay salt, 1 oz. of allspice, 2 ozs. of long pepper, 2 ozs. of black pepper, mace, cloves, and ginger 1 oz. of each, and a stick of Horse-radish. Boil all down until reduced nearly half; let it get cold, bottle it, and in three months it will be fit for use.

A Good Way with Spanish Onions.—Spanish Onions are best stewed in brown gravy; they are also good put whole into a saucepan with about $1\frac{1}{2}$ oz. of butter to each Onion, and allowed to stew for about an hour, or until done. A little pepper and salt should be added. A dessert-spoonful of Mushroom ketchup put in just at the last takes off the richness of the gravy. This is a good and proved way of cooking these.

To Preserve Truffles.—The following recipe for the preservation and use of Truffles, was obtained some years ago from the cook of the Thatched House Tavern. To preserve them: As they are found 8 or 10 inches below the surface of the earth, they require a good deal of washing and brushing before they can be applied to culinary purposes. When washed the water should be warm, and changed frequently. Truffles lose much of their flavour if allowed to get dry. Pick out the blackest, peel them carefully with a sharp knife, reject all which are the least unsound, put them into bottles as close as they can be shaken, cork them tight, and boil them for an hour in the "bain-marie."

Tomato Soup.—Stew twelve Tomatoes with a little butter, pepper, and salt (but no water), until they are tender; rub them through a sieve; add the pulp and juice to two quarts of boiling stock which has been well flavoured with vegetables. Thicken the soup with a little flour or arrowroot. Add two lumps of sugar. The addition of more butter or half-a-pint of cream may be considered an improvement, if a very rich soup is desired.

SEED SAVING AND PACKETING.

SEED, plant, flower, then seed again, is the way with most plants over and over, year after year. What a wonderful thing a seed is; what a mystery is wrapped up in a tiny grain, which will remain quiet for years, until the proper heat and moisture awaken the slumbering plant within it? But now is not the proper time to talk about growing the plant from seed; we must consider the seed as the end of the season's work of the plant. If we left the seeds to take their own course, they would be scattered on the ground near where the plant grew, or they would be conveyed to greater distances, carried by the winds, or thrown by the bursting of the seed-pods. The ways provided for the scattering of the seed, are many and most interesting, but we are not now treating of seed-scattering, but of seed-saving. If we allow seeds to grow just as they please, those of plants from warm countries will be killed by the cold of

FIG. 1 (Folding the Packet).

winter; while others will come up after lying on the ground until spring; but at the same time the seeds of weeds will come up too, and our flowering plants will be likely, while very young, to be crowded and killed by the more rough and strong young weeds. So in gardening we help Nature, by gathering the seeds and keeping them until next spring, or the proper time, and then sowing them where we can take care of the little plants when they appear, giving them the ground all to themselves, where they will not have to struggle and crowd against other competitors. If we look around among the plants, we shall see that the seeds are contained in little cases or pods of very different forms. Some of these open with a slight report, and scatter the seeds about; these you must gather just as they begin to ripen. Others just break open the pod, and need a little shaking or rubbing to make them fall out; and there are still many other kinds of seed-vessels. So we must exercise a little care in the matter. The best

way is to have some paper-boxes, and put the seed-pods in these for a few days, until they dry; then rub the seeds out, pick out the remains of the pods and stems, and then put the clean seeds on a paper, and carefully blow away any light dust that may remain among them. Mind, that when you gather the seeds, you put their names with them. Write them on a piece of card, or on a bit of stick, to keep with them while they are drying. Never leave seeds of any kind without a name with them; this will avoid much trouble and guessing. Having the seeds all dried and cleaned, they may be put away for winter. Some make little paper-bags, by pasting, very nearly like the grocer's bags, only much smaller, and these are very useful; but a bag without any paste can be made anywhere in a minute. In a garden, and wishing to give

Fig. 2 (Folding the ends).

a friend a few seeds, or in the fields or woods, when a plant is found, the seeds of which one would like to save, only a bit of paper is required to make a bag as good as the best.

How to Make Seed Papers.—Take a piece of paper (letter-paper, or smooth brown paper is as good as any), somewhat longer than wide; fold it over, but not quite equally (see fig. 1). The edge of the part of the paper folded over should come to the line between A and B in the figure. Then fold A over on to B, and both together over to a line a little below B. This is twice as easy as it seems in explaining it. Then turn the paper over, and fold one end as shown at the right hand of fig. 2. Next fold the point b over in the same manner, and tuck the point b under the fold a, and it will appear as seen on the left-hand end of the diagram. Prepare the bags by folding one end beforehand. When ready to put in the seeds, open the bag by blowing at the unfolded end; and, when the seeds are in, that end is closed by folding it just as the first end was folded. This makes a packet, from which the finest seeds will not escape, and which, for all but very large parcels, such as vegetable seeds, is as handy as need be. There is no paste required, no string to tie, and a very neat packet can be made with common paper. But, before putting the packet away, do not forget to label it. Fig. 3 shows how this is done. Like all such things, these packets are much easier to make

Fig. 3 (The Packet complete).

to describe; but, by following the directions, I think you will succeed the first time. Seeds should not be put away until dry, and then they should be kept in a cool dry place, where the mice will not find them. I cannot end this seed matter without advising that many more seeds than will be likely to be wanted by the collector himself should be saved, leaving sufficient to give away, as much pleasure may be included in the little packet with the seeds. To care for and give away flower-seeds is one of the ways in which even boys and girls can help to make the world pleasanter and better.—*Agriculturist*.

Otto of Roses.—The *Moniteur Industriel Belge*, in an interesting article on this costly perfume, says that the manufacture is largely carried on in the Valley of Kesanlik, Roumelia, the annual production of the Rose farms amounting to 4,400 pounds of the otto per year. As it requires about 130,000 Roses, weighing some 57 pounds, to make an ounce of the oil, some idea of the extent of the plantations may be formed from the above given total. The flowers are gathered in the middle of May, and the harvest continues for three weeks. The blossoms collected each day are at once worked, in order that none of the odour may be lost. The process consists in distilling them in water and then causing the water alone to undergo distillation, when the oil is skimmed from the surface. The labour is principally done by women and children, at wages of about 10 cents per day. The otto is always adulterated before transmission to market, with one-third or one-fifth its quantity of Geranium oil.

THE ARBORETUM.

THE MOST PROFITABLE VARIETIES OF TREES FOR PLANTING.

By ROBERT HUTCHISON.

THAT the necessity exists for further and more extensive introduction of varieties of trees which, by their quick growth and early maturity will repay their planters by early profits, there can be no doubt. Any one sceptical upon the point has only to look at the immense and rapidly increasing strides with which every manufacturing industry of the country is progressing. The demand for wood of every description, at enhanced prices, and the great scarcity of supply existing in many descriptions, will also corroborate the statement, and especially so when it is added that the demand is greatest, and the scarcity most apparent, in those very classes of trees of rapid development, namely, Willow and Poplar. During recent years the consumption of Willow as timber for the numerous railway networks of systems over the length and breadth of the country, has been enormous. Its universal adoption and peculiar suitability for the blocks of the brakes, &c., of waggons and other railway vehicles, have induced great scarcity of wood of large dimensions; while the more general application of Poplar of good quality for many country purposes, for which, before the introduction of the Larch disease, that tree was used, has caused a great increase in the demand for well-grown Poplar-wood. Indeed, the substitution of Poplar for Larch is, in many parts of Scotland, now very general; for in addition to the risk of failure of the Larch crop by disease, and its being a tree which requires a longer time to produce wood of relative value than Poplar, there are many more useful purposes for which the wood of this latter named tree is found to be better adapted than young Larch wood of from fifteen to twenty years' growth. Consequently, the introduction of Poplar trees in young plantations mixed with Spruce, or Scotch Fir, and Larch, to be used as nurses, seems too much neglected. The comparatively quicker maturity, for sale purposes, of the Poplar trunk, renders it a very desirable tree to be used for such purposes, and the variety of soils to which it can, without detriment to its rapidity of development, accommodate itself, makes it capable of very general application in most situations where plantations are being formed, or where any of the other common nurse trees are employed. Judiciously mixed in this manner, the Poplars may be thinned out first, along with the Scotch Firs, and thus allow the Larches to remain, if they should prove to be a healthy and thriving crop, till they become of more value from their larger growth; while in the meantime a better return is obtained from the Poplars than would have been produced had Larch alone been used instead of them, and cut when the wood first required to be thinned. The variety of Poplar most suitable for this purpose, and indeed, the best of all the class of fast-growing timber trees, is the Black Italian (*Populus monilifera*). Reference has already been made to the value of this tree in a recent issue of the "Society's Transactions," so that it is almost superfluous again to record its distinctive qualities and merits. Suffice it to say, that the more general cultivation of this useful and desirable Poplar for timber purposes is well worthy the consideration of every Scottish planter. Although this tree, like the other Poplars as a class, will thrive in almost any soil, and attain to considerable size in a very few years, it prefers, and will grow most rapidly, when planted in a deep moist loamy soil, and makes most wonderful annual growths of young wood in damp, although sandy, alluviums beside river banks or level flats. The height to which a full-grown Poplar of this variety will attain is about 120 feet, and this altitude it will reach in sixty years in suitable soil and situation. The uses to which its timber are adapted are numerous, and owing to this toughness and lightness it is well suited for any constructive purpose. In localities whence there is easy and convenient means of transit to any of the great centres of industry and manufacture Poplar wood of fair size, from about 2½ to 3½ feet diameter at the base of the trunk, will fetch from 1s. 3d. to 1s. 4d. per cubic foot, and frequently a higher price. In this respect, grown solely as a crop, this species of Poplar, in the same given number of years, will be found to be a safer and more remunerative tree to plant than almost any other. Other varieties of Poplars are also worthy of notice as being "early remunerative trees," and should be much more extensively cultivated. We refer to the common grey Poplar (*Populus canescens*), the white Poplar (*Populus alba*), both of which are decidedly worthy of much more attention than arborists have hitherto given them, and will be found to be trees of very useful value as timber for country purposes. The grey Poplar is indeed a very potent rival to the black Italian, but we prefer the latter as yielding a timber of much higher quality for every purpose than the former named tree will yield at the same age. This last mentioned tree, the grey Poplar (*Populus canescens*), is also much esteemed by many planters, and is deservedly prized for its striking foliage and cold grey tints, when skilfully blended with warmer hues in the landscape, no less than for its intrinsic merit as a useful "country wood" producing tree. It yields a light, tenacious, durable quality of timber, and is an equally rapid grower with the black Italian Poplar. The other varieties of Poplar, such as the Athenian (*P. græca*), the black Poplar (*P. nigra*), the white Poplar (*P. alba*), and the Ontario (*P. canadensis*), may be all held as fast-growing trees respectively and worthy of attention to some extent where variety of foliage and habit in a mixed plantation are desired; but as rapid producers of wood of any considerable value, we must limit our recommendations to the two Poplars previously named, *P. monilifera* and *P. canescens*. In planting Poplars it is very necessary to give due attention, in the young plantations or strips, to "clear head-room" to the young trees, for the Poplar is of itself not very prone to throw up a vigorous leader, while the rubbing and fraying of neighbouring

shoots too frequently destroys the tender soft bark of the young wood of the main stem, where early thinning has not been attended to in due season. Poplar trees in strips and plantations may thus be frequently seen to be permanently injured from this cause, and if really good specimens are desired in after years, it would be well to clear out all round the specimens left. The return from the sale of the wood of the grey Poplar of similar age to the black Italian, is about the same under ordinary circumstances, and we find that, at some timber sales lately, vigorously grown trees of the grey Poplar fetched as much as 1s. 2d. and 1s. 3d. per cubic foot, being about 2 feet in diameter at the base; and in other localities, similar, if not better, quotations were realised at recent sales for similar sizes and equal quality.

Having thus cursorily noticed the principal members of the Poplar family which are deserving of wider introduction into the woodland scenery and economic planting of this country, we shall proceed to notice those varieties of the Willow family which are worthy of more attention than they at present receive, as being trees of rapid growth, producing good and useful timber, and as being decidedly entitled to be fairly ranked amongst the foremost species of forest timber trees, as subjects worth planting, as early remunerative trees. The rapid growth of the Willow is a matter of universal admission. From the earliest Scripture times we are told of this habit of quick development when in suitable localities and situations. Thus, "they shall spring up as Willows by the water courses;" and the very derivative name "Salix," under which the whole class is enumerated, signifies to spring, and is thus characteristic of the habit so well-known of the plant. The varieties of the Willow family are well-nigh countless. Loudon enumerates some 282 varieties as well-known and in cultivation. The general features of the broad outlines of the family are their rapidity of growth. The soft, porous, light, and inflammable nature of the timber, and its general suitability for country purposes, to which ordinary hardwood and Fir are quite inapplicable, but in regard to which its toughness renders Willow or Saugh peculiarly adapted, and combine to make this tree worthy of more extensive cultivation. The covering or "cleading" of cart bottoms and railway waggons, and the manufacture of brake-blocks, form a considerable source of demand for the timber of large well-grown Willow trees, and there are many other purposes to which this wood is specially adapted, and for which it is largely used. Passing over for the present the treatment of the Willow as a crop (grown as wands), and the remunerative advantages of this mode of utilising wet lands and damp situations, where from peculiarity of situation drainage is difficult, we notice only the question of the value of the Willow as a timber-producing tree. Unfortunately, in this country the Willow is too often thrust into the background as a tree worth planting for the value of the wood, and is planted only or chiefly in damp marshy corners, where it is frequently neglected, and allowed to grow up without any regard to the formation of a good bole, or, in fact, without any reference whatever to its ulterior use. Were some little care and attention paid to this handsome species of trees, even in such waste situations, the trouble and expense would amply repay the planter. Indeed, there is no department of forestry that yields a better return than cultivating these rapid-growing timber trees, such as the Willow and Poplar. In the commercial world small profits and quick returns are now-a-days the acknowledged maxim of correct mercantile policy; and similarly in forestry, whatever plan of management, planting, or beating up be adopted, and shows the most probable prospect of future advantage, at the earliest date, is sure to be at once recommended and put into practice.

It is very difficult indeed, out of 282 varieties of the Salix or Willow family, to single out one or two of the most suitable and advantageous for general planting as timber trees; but at the same time, though there may appear 282 varieties, botanically speaking, these may be reduced to a very much smaller compass when they are treated of collectively as timber trees. In fact, they present frequently so few features of distinctive merit or difference, that the number might be very safely reduced to a much smaller list of distinctive individual trees, worth growing for their timber in suitable soils and situations throughout Scotland. Indeed, after a careful analysis of all the species, it appears that the entire list of Willows, which may be regarded as claimants for popular favour as timber trees, may be simply reduced to four distinct varieties, viz., *Salix alba* (the white or Huntingdon Willow), *Salix caprea* (Goat Willow or Saugh tree), *Salix russelliana* (Bedford Willow), and *Salix fragilis* (red wood Willow). Of these varieties, the first-named, viz., the Huntingdon Willow (*Salix alba*), is probably, when unpruned and grown naturally in favourable circumstances, the handsomest and finest of all the Willows of really tree dimensions. It is, in truth, a most picturesque and beautiful tree, whether it be regarded for its general outline and habit, or for the peculiar and distinctive whitish appearance of the foliage, which, combined with its general light and elegant outline, contribute to render this one of the most favourite trees for planting in such situations as conduce to its early and full development. Such situations are river banks in deep, damp alluvial soils in flat marshy ground, and upon those low-lying swampy situations so well known and common in Scotland, where few planters care to risk a general crop of timber trees. This Willow which we deem worthy of far more universal cultivation in this country than has hitherto been attempted, has, like many other varieties of its tribe, the advantage of thriving very well indeed in rather poor soils, and in thin sandy stretches or on damp sub-soils. Certainly most trees will thrive better in deep rich loamy soils, with rather a damp sub-soil, than in a poor thin one; but the only point of importance to be observed now-a-days is, that the soil (whatever its nature may be) shall be well drained from stagnant water, and trees of magnitude, such as the white Willow, grey Poplar, and other rapidly growing timber trees, will all benefit imme-

diately. Thus in cold upland situations not only may the grey Willow, but also the Bedford Willow (*Salix russelliana*) be grown with profit and advantage. In any situation of soil, with damp bottom, the progress made by the grey Willow is truly marvellous. The plants so situated soon attain considerable height, and rush up with clean straight boles when planted closely, and yield timber of no small value in a very few years. It has been observed that the annual increase in timber of the grey Poplar, in trees of about twenty years of age, is at the rate of about two cubic feet in certain situations—certainly no inconsiderable rent for the ground occupied by the tree—and this measurement has been verified in more than one place both in Scotland and England; and, in some soils, trees planted eighteen years ago have now attained, in strong clayey loam, fully 52 feet in altitude, and girth about 7 feet in circumference at 1 foot from the ground. The wood of the *Salix alba* is used for a variety of wright-work. It is peculiarly light, tough, and easily wrought, and is adapted for a great number of country purposes,—such as cleading of carts and waggons, railway brakes, planking and joisting boards, and for many purposes in connection with mill-wright work; tool handles, hoops, copper-work, and basket-making. Indeed, there is no part of this tree, from its thick and heavy trunk to the youngest twig, but is adapted to some use. The bark of the grey Willow abounds in tannin, but does not appear to be sufficiently appreciated, and is worthy of more notice in this country for the purposes of the tanner. In this respect it appears to be much more generally used on the Continent of Europe. The facility with which this tree is propagated, and rushes up into shape after being planted, is another recommendation to its future increased introduction. All that is requisite to commence a Willowry or plantation of this tree is to insert into the soil cuttings made from one or two years' wood (about 2 feet long) to the depth, say, of 10 inches to 1 foot. Stobs made of this tree of greater thickness, say even up to 4 to 6 inches in diameter, succeed very well in damp sub-soils, and many fine large trees have been grown from them, although, upon the whole, and in a variety of soils and situations, trees grown from the smaller sizes are preferable.

The next variety of Willow, well worthy of culture in this country, is the large-leaved or Goat Willow (*Salix caprea*), commonly called "the Saugh." Although it can hardly be said to acquire a great height and large dimensions, there are, nevertheless, examples throughout the country of immense size, considering the habits of the tree. It thrives in any soil or elevation, but will attain its highest height and dimensions in a dry, rich, deep, loamy soil, with a cool, if not dampish bottom. The wood of the Saugh is tough and elastic, having considerable lateral as well as longitudinal adhesion, and admits of a very fine polish. It is of considerable value for jobbing purposes; but the White Willow (*Salix alba*), in point of utility as a timber tree, beats this variety completely. The price which the *Salix caprea* will realise in a sale is about the same (according to district) as that of the Larch or Birch wood. It is very profitable as an undergrowth in many plantations, for in favourable seasons it will yield young shoots fully 5 feet in one year; and very suitable for the purposes of the crate-maker or basket manufacturer. The bark yields a large amount of tannin. Another member of the Willow family worthy of notice is the *Salix fragilis*, or Red-wood Willow—a tree regarding whose utility there is considerable difference of opinion. On the one hand, its timber has been condemned by some arborists as useless; and they have further asserted that the qualities usually ascribed to it are due to another species, with which they say it is confounded, viz., *Salix russelliana*; while, upon the other hand, its suitability, on account of durability, lightness, and toughness for many purposes, whether local or for ship building, for which it is well adapted, renders it worthy of more notice than it at present attracts in our plantations, where damp soil, with deep alluvial sub-soil, foster its rapid growth. Its wood is likewise available and very suitable for constructive purposes, for houses, water-wheels, planking, &c., and indeed for all country work, where a really good, clean, light, tough, elastic, and useful wood is required. One considerable drawback to this Willow is its liability to become dead in the top shoots, or "stag-headed;" and as this habit is of frequent occurrence, this variety is in much less repute than the *Salix russelliana* or *Salix alba*, as a timber tree of rapid growth. It will thrive best upon a stiff, damp, clayey, soil, with cold sub-soil. The wood is, when cut, red in the heart, with a white margin, and upon being exposed to the influence of the air for a time, the whole assumes a reddish pink hue of agreeable appearance, and of a consistency easily wrought, and of a very useful texture for any domestic or rural purpose.

The other species of Willow which has been mentioned as worthy of extended cultivation in this country is the Russell or Bedford Willow. Resembling as it does the *Salix fragilis*, already described, it is rather more graceful and elegant in its foliage and contour; and indeed, in the case of large and well-grown trees, the *Salix russelliana* exhibits a far finer outline than any other of the congeners of this family. Its rapidity of growth is fully equal to that of the *Salix alba*, and far superior to that of the other members of the Willow tribe already described. Its timber is about equal to that of the *Salix alba*. While light, tough, elastic, and unlikely to crack or split, its timber is highly prized in the building of manufactories, and for flooring and such like purposes; for its non-combustive properties, coupled with its non-liability to shrink or crack, render it very useful in the building of many edifices,—such as mills, manufactories, granaries, &c. It is also, like its other neighbours of the Willow and Saugh tribes, greatly used for cleading cart and waggon bottoms, making railway brakes, lining coal-pits and stone or lime quarries, and for almost any purpose connected with rural economy. This Willow succeeds best in a deep moist soil of medium description, but is decidedly unsuited to situations where water is stagnant in the sub-soil. It will also thrive and produce good timber upon cold clayey soil, if there

be due regard to drainage of the till beneath. Upon the whole, the *Salix Russelliana* is very decidedly a tree to be extensively planted in conjunction with the *Salix alba* and *Salix fragilis*, upon exposed uplands for timber purposes, and in such situations it will yield a quick and good return to the planter. It should be grown in masses, for in such circumstances it is far more profitable than when planted as a single specimen or hedge-row tree, or when mixed with others whose too rapid side-spreading growth may interfere with its head or stem.—*Highland Society's Transactions*.

GARDEN STRUCTURES.

TROPICAL FRUIT HOUSES.

MANY of the well-known fruit-trees of the tropics might be made, under proper treatment, as indicated in our illustration, to yield freely their delicious fruit in this country. Last year a Papaw tree (*Carica Papaya*), about 6 feet in height, produced several of its fine fruits in great perfection in one of the houses in the Jardin des Plantes at Paris. They were of the size of a Cantaloupe Melon, and of a somewhat similar form. They ripened perfectly in a temperature varying from 59° to 68° Fahrenheit. In the beginning of the present month might have been seen, in the same establishment, a gigantic specimen of *Monstera deliciosa*, which ripened its succulent fruit in considerable abundance. This fruit, which may be said to resemble an elongated Pine-apple, exhales an exquisite perfume, and its flavour is not unlike that of a Pine-apple. Few of us will have forgotten that the Mangosteen fruited at Syon a few years since, notwithstanding the difficulties that appeared to beset its successful culture. It was also at Syon House that the Cocoa-nut Palm (*Cocos nucifera*) was, for the first time in Europe, in 1863, made to produce fruit. Bananas, too (see p. 410), as is well known, especially *Musa Cavendishii* and *M. paradisiaca*, if planted out under glass in a suitable temperature, are well known to yield fruit abundantly. The Vanilla lends itself so freely to artificial culture, when care is taken to fructify its exceedingly ephemeral flowers at an early hour in the morning, that its culture, we doubt not, might be turned to good commercial account, as its slender pods, often 10 or 12 inches in length, bear a high price for flavouring confectionery, and for various culinary purposes. The Brazilian Chestnut tree (*Bertholletia excelsa*), the fruit of which is so well known under the name of Brazil Nuts, submits readily to judicious artificial culture, as does also the Date Palm (*Phoenix dactylifera*), the delicious and highly-saccharine fruits of which may be thus artificially produced in great perfection. The Coffee tree of Bengal and Ceylon, forming a very neat and pretty shrub, may be made to fruit freely in our hot-houses, even in a very young state. The Guava (*Psidium Cattleianum*), too, may be cultivated with success. There are several species or varieties of this genus, all of which are of convenient size for growing under glass, scarcely any of them exceeding 15 or 20 feet in height when fully grown. The last plant we shall name, but

without by any means exhausting a list which might be very much extended, the Clove tree (*Caryophyllus aromaticus*), which yields the Cloves of commerce, ought, on no account, to be overlooked. This handsome evergreen tree is worthy of growth even for ornament, and, though a native of the tropics, will thrive in the open air in some parts of Europe, even of England, but it is only seen in its full beauty as a handsome evergreen tree from 20 to 30 feet high, when cultivated under glass. As evidence that a great number of other fruit-bearing tropical trees may be so successfully treated in Europe as to compel them to produce their curious and, in many instances, extremely delicious fruits, the following list of mere names may be appended:—*Anona Cherimolia*, a Peruvian tree, producing a fruit which the creoles of the West Indies consider to be the most delicious in the world; the Bread-fruit tree (*Artocarpus incisa*); the Carob tree (*Ceratonia Siliqua*); the Calabash tree (*Crescentia Cujete*), the gourds of which, wherever it grows wild, take the place of pottery ware among the natives; the Madagascar "Plum" (*Flacourtia Ramontchi*); the Genipa tree (*Genipa americana*), producing a fruit of the size of an Orange, of such agreeable flavour, that in Surinam the fruit is called the Marmalade box; the Locust tree (*Hymenaea Courbaril*), a tree of enormous

Section of a Tropical Fruit-house.

growth, and attaining a great age, some specimens in the forests of Brazil being, it is computed, antecedent in date to the Christian era. While young, this tree would be perfectly manageable under glass. Then there is the Malay Apple (*Jambosamalacensis*), an Indian tree, the fruit of which is much esteemed. The Monkey-pot tree (*Leeythis ollaria*), is so named from the urn-like shape of the fruit or husk, which has a lid that falls off when the seeds, or rather nuts, are ripe, and allows them to fall to the ground. The nuts of *L. zabucajo* are said to be very superior to those of *L. ollaria*, both in texture and flavour, and also to the common Brazil Nut. The Alligator Pear tree (*Persea gratissima*), the Tallow tree of China (*Stillingia sebifera*)—these, with the Tamarind tree (*Tamarindus indica*), and many others of curious and interesting character, are sufficient to show what an interesting and beautiful collection of tropical fruit trees might be grown without much difficulty; and it is evident that a hothouse, devoted entirely to fruit-bearing tropical trees, would be much more instructively interesting than one in which a miscellaneous collection was placed, without any special intention. In the annexed cut Pine-apples are shown on the side-shelves, the pipes beneath which convey a large supply of genial heat; but there are, doubtless, other pipes at some depth beneath the centre bed calculated to convey a gentle heat to the soil itself in which the fruit trees are growing.

H. N. H.

Wooden Curvilinear Conservatories.—The description given (see p. 369), of a conservatory erected in Mr. Ley's nursery, Croydon, is calculated to lead people to believe that the curvilinear form of roof in wood, and also the substitution of straight for curved glass, are novelties. At the Royal Horticultural Society's

meeting, at Birmingham, in 1872, a curvilinear conservatory, with wooden spandrels on trusses, without tie rods, was shown by a well-known firm; but, before it had been erected many hours, the trusses, though deep and heavy, showed signs of caving-in, and it was eventually found necessary to support each truss by means of an iron column under the centre. We can conceive nothing more out of place than the use of light curved wooden trusses for the main supports of roofs. To be what is called rigid, which is a stern necessity, a timber roof truss must be heavy and well-braced together. We are no advocates for iron in the construction of horticultural buildings; but where rigidity, great strength, and, at the same time, elegance, are required, it is absolutely necessary to adopt it; and, for roof principals, or trusses, there is no stronger or better form of construction than the iron tubular system. As a proof of the confidence placed in this system, we may mention that we have been entrusted with the construction of the Eastbourne Pavilion, the Bournemouth Winter Garden, and other great works on that principle. The use of straight instead of curved glass was exhibited in our prize house at Birmingham, in 1872.—FLETCHER, LOWNDES, & Co., Great George Street, Westminster.

MATERIALS FOR GLASSHOUSES.

WHAT are the materials to employ in the construction of these has become an important question, and one that is continually forcing itself in anything but an agreeable way upon us, viz., in the shape of decayed sash bars, rafters, and wall plates, that much sooner go rotten than they were expected to do. Cheap glass has been the means of increasing the area of fruit and plant structures a hundredfold; and great improvements have been made in the forms of different erections for horticultural purposes. Light, the sheet anchor of good cultivation, both as regards flowering and fruit-bearing plants, so deficient in old houses, has been secured in these modern buildings; very great saving, too, has been effected in labour through facilities in the way of ventilation; in fact, everything possible has been done but rendering them more durable. Unfortunately, this would appear to be a matter lost sight of, comparatively speaking, for, undoubtedly, houses for gardening purposes built of late years will not last anything near the time the old ones did. Nay, further, many an old plant-house or Vinery built a quarter of a century ago will yet outlast similar structures that are not many weeks old. And this is not a matter to create surprise, if we only possess a knowledge of, and take the trouble to examine, the materials of which they are made. Rarely do we now meet with a glass structure of any description in which the timber used is other than yellow pine; and, if we consult a dozen or any other number of builders, they will, one and all, tell us it is the best. But surely the evidence of dear-bought experience is not to go for nothing in the balance with mere assertion. Yellow pine may be the best and most durable in buildings not under the exceptional influence of damp, such as an ordinary dwelling house; but I say distinctly it is not the material to use in the construction of either cool or hot plant and fruit houses, and that it will not last half the time that good red deal will; and the redder the latter is, *i.e.*, the more resin it contains, the longer it will resist the inroads of moisture, which is the great source of decay in buildings of this description. These conclusions I have arrived at through a lengthened personal experience with old and new houses, used for garden purposes of all descriptions, confirmed by observations which I have been enabled to make in places innumerable, where I have ascertained all the particulars necessary as to the age of the different houses, the purposes they have been used for, and data in every way bearing upon the subject. I had a couple of houses of yellow pine put up adjoining one of red deal that had been erected fifteen years, and used from the first as a moist plant stove; the new houses, after eighteen years' similar wear in growing plants that required moisture, were so rotten, that, after strengthening and propping up in all ways, they had to be re-built through sheer inability to make them hold together. The rafters, sash-bars, and every part were so decayed that the blade of an ordinary pruning knife could be easily pushed into the wood in all directions. The old house is standing yet, having all the time been used as a moist house, and to all appearance will last another twenty years. This is one of a number of instances in which I have had an opportunity of seeing the unsuitable nature of anything in the shape of yellow or white deal for hothouse building. If the erection is simply a place in which to grow plants that only require protection from frost, as an ordinary greenhouse or a late Vinery, then inferior sorts of deal may do, and last for a length of time; but for the cultivation of stove plants that need continuous moisture, more or less, in the atmosphere, such wood is totally unsuitable, and should never be used; neither should it be selected for Pine stoves, early Vineries, Cucumber or Melon pits—all of which, requiring moisture, hasten its decay. And I maintain that in the construction of ordinary plant and fruit houses

the principle we go upon is not sound, unless, so far as the glass and wood-work go, they are such as to be adapted for any purpose hereafter required—for plants or fruits that want either a dry or moist atmosphere. Look, for instance, at the numbers of cool plant houses that are turned to the growth of stove plants, as also late Vineries into early forcing work, where the moisture used is much in excess of the original quantity; and even for houses where the subjects grown continuously are such as require no more moisture in the atmosphere than ordinary greenhouse plants, good red deal will last much the longest. I saw this autumn a whole range of houses that had never been used for the cultivation of anything except greenhouse plants, which were being re-built, having become so rotten that they would not stand, after thirty years from the time of their construction; whereas, if red deal had been used, they would have lasted much longer. The old system of hothouse building has, within the last forty years, been completely revolutionised. The massive, heavy timber that formerly was employed has given place to such as is not more than half the weight, so as to admit a maximum of light to the plants grown. This was a vast improvement, consequent upon the better understood requirements of the different plants, and a disposition to produce them in something approaching their natural condition, as opposed to the weakened things that in times past merely existed. But this great reduction in the bulk of the timber employed has naturally reduced the strength, and left correspondingly less to resist the unavoidable inroads of decay; consequently, instead of using a worse description of timber than formerly, we should have at all events kept up to the standard of times past, and this is just what we have not done, and are not at the present time doing. I can see on all sides plant and fruit houses being erected that twenty years hence will be virtually tumbling about the ears of whoever may then have to deal with them; and these, be it observed, are not what are understood as cheap or low-priced erections, but such as cost money enough to command better materials. The natural requirements of great quantities of the plants at the present day cultivated under glass, and the treatment we now give to many long ago introduced to the country, by the use of much more moisture in the atmosphere in their cultivation than formerly, hastens the decay of the wood even when it is of the best possible description, and renders the use of such as is inferior a very serious mistake. The use of iron in the construction of ordinary plant and fruit-houses has met with little favour—why, it would be difficult to say; only in this, as in most other things, when once we get into a certain groove it is a most difficult matter for us to get out of it. It is sometimes urged that the inside drip from iron—more or less unavoidable where the plants grown are such as require a moist atmosphere—is injurious to them. It often happens that the knowledge of a house being built of iron, and so far not liable to decay through the action of moisture, causes its long neglect in painting, to an extent that would never be allowed, if constructed of wood; and the consequent rust discolours the water which is condensed on the roof, and may, in places where it drips upon the foliage, discolour it. But there is no reason why such omission in painting should occur, and the same objection might be raised against the employment of iron for numbers of purposes where, for various reasons, its use is indispensable. Providing that it be kept properly painted, no injury, either real or imaginary, will arise. I can point to iron houses that have been in existence over eighty years, used for early forcing and the cultivation of both stove and greenhouse plants, without the slightest injury having occurred; and, so far as wear goes, they may last another eighty years. Another objection raised against iron sash bars is, that their expansion in hot weather has a tendency to crack the glass. This will not occur if the glass is not put in too tight. Even in the case of wood, breakage will happen if too tight glazing is practised. The importance of this subject will be apparent to all who are about to build houses, especially such as are intended to be used for the growth of plants and fruits that require the presence of a large amount of moisture in the atmosphere. The recent reduction in the price of iron is a consideration in favour of iron houses, and will, no doubt, influence its use for horticultural purposes. T. BAYNES.

The Snow Plant.—Can Mr. Andrew Murray or any of your readers tell me what plant is mentioned in the following note from a Denver paper?—"No grander object is met in the mountains about that place than the Snow plant. It is an inhabitant only of the higher rocks, being rarely found below an altitude of 4,000 feet, and its glorious crimson spike of flowers may be seen, early in May, forcing itself through the snows which at that period cling about the sides of our Pine forests. The portion of the plant which is visible above the soil is a bright rosy-crimson in colour, and presents the very strongest contrast to the dark green of the Pines, and the

'shimmer of the snow.' Its root is succulent, thick, and free from moisture, attaching itself to the roots of other plants, principally to species of the Pine family. Hence, it is among those members of the vegetable world which are known to botanists as parasites, and may, therefore, be said to be incapable of cultivation."—Q.

THE LIBRARY.

PHARMACOGRAPHIA.*

THIS is in every way an excellent and remarkable book on the medicinal products of the vegetable kingdom. The capacity of the authors to deal with this subject, and their thoroughly conscientious way of expressing in this work the great knowledge they possess of it, leaves us nothing to do but explain the plan of the work and give an illustration of how each subject has been treated. It was the desire of the authors not only to write upon the general subject, and to utilise the thoughts of others, but that the book which they had decided to produce together, should contain observations that no one else had written down. It is, in fact, a record of personal researches on the principal drugs derived from the vegetable kingdom, together with such results of an important character as have been obtained by the numerous workers on *Materia Medica* in Europe and America. Unlike most of their predecessors in Great Britain during this century, the authors have not included in their programme either Pharmacy or Therapeutics; nor have they attempted to give their work that diversity of scope which would render it independent of collateral publications on botany and chemistry. While thus restricting the field of their inquiry, the authors have endeavoured to discuss with fuller detail many points of interest which are embraced in the special studies of the pharmacist; and at the same time have occasionally indicated the direction in which further investigations are desirable. A few remarks on the heads under which each particular article is treated, will explain more precisely their design. The drugs included in the present work are chiefly those which are commonly kept in store by pharmacists, or are known in the drug and spice market of London. The work likewise contains a comparatively small number which belong to the pharmacopœia of India: the appearance of this volume seemed to present a favourable opportunity for giving some more copious notice of the latter than has hitherto been attempted. Supplementary to these two groups must be placed a very few substances which possess little more than historical interest, and have been introduced rather in obedience to custom and for the sake of completeness than on account of their intrinsic value. Each drug is headed by the Latin name, followed by such few synonyms as may suffice for perfect identification, together, in most cases with the English, French, and German designation. In the next section, the botanical origin of the substance is discussed, and the area of its growth or locality of its production is stated. Except in a few instances, no attempt has been made to furnish botanical descriptions of the plants to which reference is made. Such information may readily be obtained from original and special sources, where, moreover, figures of the plants may not unfrequently be found. Under the head of history, the authors have endeavoured to trace the introduction of each substance into medicine, and to bring forward other points in connection therewith, which have not hitherto been much noticed in any recent work. This has involved researches which have been carried on for several years, and which has necessitated the consultation of many works of general literature. The exact titles of these works have been scrupulously preserved, in order to enable the reader to verify the statements made, and to prosecute farther historical inquiries. The following account of the now popular Podophyllin drug, the product of a plant long known to many of our readers, shows the way the authors have done their work:—

Rhizoma Podophylli.

Radix podophylli; Podophyllum Root.

Botanical Origin.—Podophyllum peltatum, L., a perennial herb growing in moist shady situations throughout the eastern side of the North American Continent from Hudson's Bay to New Orleans and Florida. The stem about a foot high, bears a large, solitary, white flower, rising from between two leaves of the size of the hand, composed of five to seven wedge-shaped divisions, somewhat lobed and toothed at the apex. The yellowish pulpy fruit, of the size of a pigeon's egg, is slightly acid and is sometimes eaten under the name of May Apple. The leaves partake of the active properties of the root.

History.—The virtues of the Rhizome as an anthelmintic and emetic have been long known to the Indians of North America. The

plant was figured in 1731 by Catesby, who remarks that its root is an excellent emetic. Its cathartic properties were noticed by Barton in 1798, and have been commented upon by many subsequent writers. In 1820, Podophyllum was introduced into the United States Pharmacopœia, and in 1864 into the British Pharmacopœia. Hodgson published in 1832 in the *Journal of the Philadelphia College of Pharmacy* the first chemical observations on the Rhizome, which now furnishes one of the most popular purgatives, the so-called Podophyllin manufactured on a large scale at Cincinnati and in other places in America, as well as in England.

Description.—The drug consists of the rhizome and rootlets. The former creeps to a length of several feet, but as imported is mostly in somewhat flattened pieces of 1 to 8 inches in length, and 2 to 4 lines in longest diameter; it is marked by knotty joints showing a depressed scar at intervals of a few inches which marks the place of a fallen stem. Each joint is, in fact, the growth of one year, the terminal bud being enclosed in papery brownish sheaths. Sometimes the knots produce one, two, or even three lateral buds, and the rhizome is bi- or tri-furcate. The reddish-brown or grey surface is obscurely marked at intervals by oblique wrinkles, indicating the former attachment of rudimentary leaves. The rootlets are about half a line thick, and arise from below the knots and adjacent parts of the rhizome, the internodal space being bare. They are brittle, easily detached, and commonly of a paler colour. The rhizome is mostly smooth, but some of the branched pieces are deeply furrowed. Both root-stock and rootlets have a short, smooth, menly fracture; the transverse section is white, exhibiting only an extremely small corky layer and a thin simple circle of about twenty to forty yellow, vascular bundles enclosing a central pith, which, in the larger pieces, is often 2 lines in diameter. The drug has a heavy narcotic, disagreeable odour, and a bitter, acrid, nauseous taste.

Microscopic Structure.—The vascular bundles are composed of spiral and scalariform vessels intermixed with cambial tissue. From each bundle a narrow-tissed, wedge, or crescent-shaped liber-bundle projects a little into the cortical layer. This, as well as the pith, exhibits large thin-walled cells. The rootlets are, as usual, of a different structure, their central part consisting of one group of vascular bundles more or less scattered. The parenchymatous cells of the drug are loaded with starch granules; some also contain stellate tufts of oxalate of calcium. Tannic matter is present in very small amount as proved by perchloride of iron.

Chemical Composition.—The active principles of Podophyllum exist in the resin, which, according to Squibb, is best prepared by the process termed re-percolation. The powdered drug is exhausted by alcohol, which is made to percolate through successive portions. The strong tincture thus obtained is slowly poured into a large quantity of water acidulated with hydrochloric acid (one measure of acid to seventy of water), and the precipitated resin dried at a temperature not exceeding 32° C. The acid is used to facilitate the subsidence of the pulverulent resin which, according to Maisch, settles down but very slowly if precipitated by cold water simply, and if thrown down by hot water fuses into a dark brown cake, which, however, has the advantage of being nearly free from berberine. Resin of Podophyllum thus prepared is a light, brownish-yellow powder with a tinge of green, devoid of crystalline appearance, becoming darker if exposed to a heat above 32° C., and having an acrid, bitter taste. The drug yields 3½ to 5 per cent. of this resin, which is very incorrectly called Podophyllin. The product is the same whether the rhizome or the rootlets are exclusively employed. It is soluble in caustic, less freely in carbonated alkalis, and is precipitated, apparently without alteration, on addition of an acid. Ether separates it into two nearly equal portions, the one soluble in the menstruum, the other not, but both energetically purgative. From the statements of Credner, it appears that if caustic lye is shaken with the ethereal solution, about half the resin combines with the potash, while the other half remains dissolved in the ether. If an acid is added to the potassic solution, a red-brown precipitate is produced which is no longer soluble in ether nor possessed of purgative power. According to Credner, the body of greatest purgative activity was precipitated by ether from an alcoholic solution of crude Podophyllin. It was, however, found, after due purification, to be soluble in ether. F. F. Mayer, of New York, found Podophyllum to contain, beside the resin already mentioned, a large proportion of berberine, and a colourless alkaloid, a peculiar (?) acid, an odoriferous principle which may be obtained by sublimation in colourless scales, and, finally Saponin. From all these bodies the resin, as prepared for pharmaceutical use by Squibb's process, is free, provided that, after precipitation, it is well washed with hot water to remove the berberine. An aqueous extract of Podophyllum is devoid of cathartic power.

Uses.—Podophyllum is only employed for the preparation of the resin (*Resina Podophylli*) which is now much prescribed as a purgative.

* "Pharmacographia: A History of the Principal Drugs of Vegetable Origin, met with in Great Britain and British India." By Friedrich A. Flückiger (Phil. Dr., Professor in the University of Strassburg) and Daniel Hanbury (F.R.S., Fellow of the Linnean and Chemical Societies of London). London: Macmillan & Co. 1874.

THE KITCHEN GARDEN.

IRRIGATION OF VEGETABLE GARDENS.

THE neighbourhood of Sens supplies to Paris a large share of the culinary vegetables required by the yearly increasing population of that metropolis. One of the principal advantages enjoyed by the market-gardeners of Sens is the abundant supply of water furnished by the always brimming River Vannes. From this source, irrigation, at suitable periods of the year, can be easily obtained to any extent required, and this facility renders the neighbourhood of Sens quite a lesser Egypt in point of fertility. The well-known fertilising power of the annual inundation of the Nile might long ago have taught other gardeners than those of Sens what extraordinary advantages may be derived from the natural or artificial overflowing of rivers, especially in flood time, when the water brings down fertilising matter of various kinds, which, deposited evenly over the fields and gardens so irrigated, is more beneficially stimulative than the less regular application of strong artificial manures; or even guano, which cannot be applied with the same moderation and regularity as the gradual water-spread stimulants furnished by irrigation. There are market gardens by the acre close upon the banks of the Thames and other of our tidal rivers, but one does not hear of the periodical high tides being utilised, while they are, at the same time, kept under due control by fitting means. It appears that the gardening craft of Sens is about to be partially deprived of the great advantages it has so long derived from the copious flow of the Vannes; inasmuch, as it has been determined to make use of that source for supplying Paris with a purer supply of water than it has hitherto enjoyed. The works are already far advanced, and, as a natural consequence, the level of the waters of the Vanne have already fallen to a point which imposes heavy labour on the gardeners of Sens, who form a very numerous class in that locality. It will be interesting to watch their proceedings, and the methods by which they will be enabled to surmount their present difficulty, which, with characteristic French ingenuity, they will, doubtless, accomplish. The lesson may possibly be turned to good account in this country.

II.

SHELTER FOR KITCHEN GARDEN CROPS.

SCARCELY a year passes without teaching us lessons upon the importance of shelter for growing crops. There are so many things in a garden that are tender, or only half-hardy, that gardeners, more than any other class, realise the terrible meaning of late frosts and scathing east winds. The year 1871 will be long remembered for its frosts, and winds nearly as late as midsummer. Here, in South Yorkshire, where we are high and inland, the thermometer did not fall below 33° or 34°, though it did so in many places in the southern and midland counties; but the east winds told upon us with destructive effect. We have seldom seen fruit trees so laden with bloom as they were this year before the winds came; but the result has been scarcely a bushel of Apples and Pears in the whole district. Vegetables, too, were brought to a complete stand-still. The experience thus gained has made us think more than usual of the advisability of returning to the old practice of mixing crops, by running rows of Peas or other tall-growing vegetables at intervals between crops of such things as Potatoes, French Beans, or Cauliflowers, &c., instead of confining each to quarters by themselves—an arrangement by which ground is saved and convenience gained. It is surprising how much a row of Pea-sticks even will break the blast, and a hedge of Black Currant bushes run across a quarter is almost as good as a wall. Raspberries, also, may be used with signal effect for the same purpose. We have noticed the important advantages of such slight protectors this year in many instances. We are acquainted with some gardens from 6 to 8 acres in extent within the walls, where everything is arranged in squares, over which the wind sweeps as scathingly as if they were in the open field. How much better would it be if in such large kitchen gardens the quarters were sub-divided by close rows of pyramid fruit trees, Currant bushes, and in summer by the growing of Peas, Scarlet Runners, and similar crops. The boundary walls of a kitchen garden are undoubtedly a great protection themselves, but when the area enclosed exceeds 3 or 4 acres, it is obvious that they can afford but little shelter to the central portions of the ground, and it is certainly better in such a case to run a central wall through the garden—a plan against which no objections can be urged that we can see, though in mostly all new kitchen gardens that we know of, the middle wall has been discarded, seemingly for the sake of permitting sweeping lengths of ribbon-borders only. Walls, however, and other modes of protection of a similar kind, are of secondary importance to the site of the garden. From north and east winds, and from those western hurricanes which are so destructive to such Apples and Pears as have escaped spring frosts, there is no protection like a

belt of tall trees or a piece of rising ground between these points and the garden, though such objects should not be so near as to be injurious by their shade. Here we are completely shut in from the north and west by tall Elms, and in stormy weather, though the wind "roars and rustles" outside the barrier, it is scarcely felt inside the garden. The terrific gale which passed over the country last spring raged with extreme fury here, prostrating many gigantic trees just outside the walls; but, thanks to the Elms in question, it was comparatively little felt in the garden, though outside of the belt no glass roof could have resisted the wind.—*The Gardener.*

GARDENING FOR THE WEEK, AND AMATEUR'S CALENDAR.

Flower Garden and Pleasure Ground.

WHEREVER a system of spring bedding is intended, the planting of the various species of plants and bulbs should now be finished as soon as possible, in order to give the plants used for the purpose time to establish themselves in their new position before severe frost or wintery weather sets in. It is also quite time that all bulbs used for this purpose should be in the ground, in order to induce, as much as possible, early flowering, and the consequent early ripening, of the bulbs, so as to admit of their being taken up by the time that the beds are required for the summer bedding plants. In some instances, where the summer flower garden may not be a conspicuous object from the windows of the residence, or where it may be at a considerable distance from it, or in cases where a garden is laid out in some part of the grounds for the express purpose of growing spring flowering plants and early bulbs—under such circumstances it may possibly be considered unnecessary to plant the beds of the summer flower garden with spring flowering plants, thus compelling them, as it were, to do double duty, and subjecting them to exhausting effects. It is true that much has been said and written against the so-called unsightly masses of bare earth which flower gardens generally present during the ensuing five or six months. In reality, however, there is much less in this than might at first sight appear to be the case; as, taking one season with another, during at least one-half the above-named period the surfaces of all flower beds are either frost-bound or hid from view by their winter mantle of snow, during which time it is quite immaterial as to whether they are furnished or otherwise. After all, too, there is nothing so very unsightly in neatly-formed beds of fresh soil, composing an artistically-designed garden surrounded by closely-cut and well-swept green sward. But, wherever it may be intended to forego the use of winter and spring flowers in such gardens, the beds should, nevertheless, be neatly dug over as soon as the summer bedding plants are removed; the Grass should be again mowed, if at all necessary, swept, and well rolled down, and put into the best order possible for the winter; while in the soil yard, or in some other out of the way, but convenient place, preparations should be made for collecting and preparing the necessary quantity of fertilising materials, with which to enrich the flower beds, and borders for the following season. This compost may, of course, consist of various materials, such as well-rotted stable-yard or hot-bed manure, well decayed leaf soil, and, if procurable, a portion of the top spit from an old pasture, or sound maiden loam in any form, which should be well chopped up, and mixed with the other ingredients, and should be frequently turned during the winter months, and applied to the beds and borders in spring, in accordance with the probable requirements of the different kinds of plants, which are intended to occupy them. This circumstance should always be kept in view, as for some varieties of bedding plants, the soil can, as a rule, hardly be rendered too rich; while for others, highly enriched soil is by no means desirable, as it tends to produce an over-luxuriance as regards foliage, and a corresponding paucity in flowers. The bulbs and tubers of such plants as Cannas, Dahlias, Gladioli, Tigridias, Caladium esculentum, Commelina celestis, Marvel of Peru, &c., should now be taken carefully up, and after being well dried should be stored in some secure place, out of the reach of frost. The roots of such varieties of plants as the three last-named may, with advantage, be packed in Cocoa-nut fibre, dry earth, ashes, or sand. Pot up rooted layers of Carnations and Picotees, rooted cuttings of choice Pansies, &c. Cut down the decaying flower stems of Hollyhocks and other hardy herbaceous plants, and any very choice or scarce varieties of the former, may for greater safety, and for the purpose of more rapidly increasing them, be lifted and potted. Keep lawns and walks as free as possible from falling leaves, worm casts, and other littery matter. Attend to the stock of bedding plants, giving air in abundance whenever the state of the weather will permit, and water only when it is really required.—P. GRIEVE, *Culford, Bury St. Edmunds.*

Bouquet Flowers in Season.

Our flower markets are now abundantly stocked with Dahlias, which, though not perhaps strictly speaking bouquet flowers, may, nevertheless, be ranked amongst useful table ornaments. For bold arrangements in halls, too, their rich colours display themselves with excellent effect. It is, however, somewhat difficult to arrange them nicely, as, in some instances, the flower-stalks are not of sufficient thickness to carry the blooms erect. In order to remedy this, a steel wire should be bound up the stem, which it will support most effectually. Plenty of the handsome spikes of the purplish-blue *Veronica*, too, may now be obtained; these associate well with light-coloured Dahlias, and, at this season, are in other respects most useful, as they will remain fresh in water for over a week. If Ferns are selected for mixing with such flowers as those just enumerated, they should consist of strong growing varieties, as fronds of the delicate Maiden-hair and similar kinds would not be in keeping with flowers of such large size. A few sprays of the old-fashioned *Fuchsia fulgens*, placed amongst dark-coloured Dahlias, look well. This *Fuchsia* is now in perfection, and, though not much grown for cutting, is well suited for that purpose, its handsome drooping bells and fine foliage being alike ornamental. *Cyclamen* blooms, though not plentiful, are beginning to make their appearance, but these do best in a tube glass, intermixed with a few fronds of delicate Ferns; in this manner they form very elegant little floral ornaments either for placing on the dinner-table or in the drawing-room.—A. HASSARD.

Indoor Plant Department.

Chrysanthemums which are now fast coming into flower, should hold a prominent position in conservatories for some time to come. If the house in which they are to be placed is tolerably light, these plants will bear setting moderately close, yet do not crowd them, or the leaves will suffer and begin to decay before the flowering is over. The later varieties, which have been prepared to succeed the earliest flowering kinds, should be well attended to as regards thinning the flowers and removing suckers and useless side-shoots, which, if allowed to remain, impoverish the plants and correspondingly injure their ability to flower. If mildew presents itself, at once apply flowers of sulphur. Any store plants, or such as require through the winter an intermediate house temperature, should now be removed from the conservatory to warmer quarters, or they will suffer; for the temperature of conservatories for the next six weeks ought to be kept no higher than just sufficiently warm to expel damp. From 40° to 45° at night will be ample, as a higher temperature shortens the flowering period of the greater portion of the occupants; it also stops roof climbers, or any plants that are planted out permanently in borders, from making growth at this season, when the less excitement they receive the better. Now that plants used for roof drapery are comparatively at rest and their growth matured, they should be thoroughly cleared of any insects with which they may happen to be infested. The first lot of *Hyacinths* should be got into heat at once if they have pushed sufficiently, more especially as regards abundance of roots. Plants of *Narcissus* should be similarly treated. The best winter-flowering scarlet *Geraniums*, that will stand heat, should now receive every attention. A little heat, plenty of light, and no more water than will just keep the roots in action and the plants from flagging, will induce a greater disposition to flower than any other kind of treatment. Give every attention to the first lot of *Primulas* and *Cinerarias*, which should now be throwing up flower-trusses. Keep the *Primulas* as near the glass as possible, and give them just sufficient water at the roots to keep the soil in a healthy condition. *Cinerarias* should have more water, and the atmosphere for the latter must not be so dry as for the *Primulas*, or they will lose their under leaves. Pot more *Hyacinths*, *Narcissi*, *Crocuses*, *Tulips*, *Hoteia* (*Spiraea japonica*), Christmas Roses, and the old *Scilla sibirica*, which is invaluable for its colour, and requires little or no heat to induce it to open its beautiful blue flowers. *Poinsettias* and *Euphorbias* will require a moderate amount of heat, say 60° night temperature, to induce them to bloom freely. A few plants of *Centaurea* (any of the varieties, but *ragusina* is the best) may now be introduced into the conservatory with advantage. *C. ragusina* looks well anywhere; its silvery leaves are excellent for cutting for vases or even for bouquets. Some of the early struck plants of *Hydrangea* will, in all probability, be showing flower, and should therefore be introduced at once into a little heat; they will come in at a time when they will be much wanted, and will last in good condition for weeks. Pot late struck *Hydrangeas*, using peat and a little sand for a portion of the stock, with loam and sand for the others; by this means in all probability the two colours, blue and pink, will be secured. *Pelargoniums* that have been shaken out and re-potted should stand near the glass and receive as much light as possible. If there is not a house or pit in which they can be placed by themselves, they should be placed in the best situations available,

where they can be accommodated with a night temperature of from 40° to 45°; give plenty of air in the day-time, and keep the soil much drier than is required for most other plants, or the roots will suffer and the shoots become unduly attenuated. Where *Pelargoniums* are grown with the view of forming specimens, they should have all their shoots tied out, bringing them down as low as the rim of the pot. Seedling herbaceous *Calceolarias* should now be potted, using for the purpose large-sized thumb pots; the soil should be good turfy loam, three parts; sifted leaf-mould, rotten dung, and sand, two parts. Keep them near the glass, with an atmosphere somewhat humid—similar, indeed, to that recommended for *Cinerarias*. Plants of *Lilium auratum* should now be re-potted, taking care not to injure the roots in the operation. Remove the dead tops from *L. lancifolium*.

Indoor Fruit Department.

Fermenting leaves and litter should now be placed on the inside border of the early Vinery to the depth of about 2 feet. In addition to furnishing heat to the roots, this supplies sufficient atmospheric warmth for a considerable time without the aid of fire-heat. Keep the temperature at 55° at night, until growth is somewhat advanced. If the cold outside is severe, a little fire-heat will be needed to maintain this warmth, but not otherwise. The temperature may be allowed to rise to 60° without air during the day-time, and 65° with it. Dew the roots overhead morning and evening with the syringe, using water not colder than the temperature of the house; close the ventilators early in the afternoon, and always aim at securing as much natural heat as possible, as it is the best for promoting healthy growth. The early Vinery will now be a suitable receptacle for both soft and hard-wooded plants intended to furnish cut flowers for decorative purposes. All kinds of heating apparatuses connected with forcing-houses should now be examined and put thoroughly in order, as much damage is frequently the result of neglecting this until too late. Remove from the pipes, along with the water, any sediment that may have accumulated in them during the past season, refill them with clean water, and, when empty, take the opportunity of tightly cementing any leakage that may exist about the joints. Portland cement, mixed to a mortar-like consistency, is the best material to use for this purpose; it is as hard and durable as iron filings, when properly set. All the most decayed-looking leaves should be removed from Vines, especially from those on which fruit is still hanging. A little artificial heat applied to these now and then, assists greatly in obviating damp. The second batch of Queen Pines should now be allowed to go to rest, by lowering the temperature and keeping them moderately dry at the root; 55° with fire-heat will be sufficient for them. Growth among any kind of Pines should not now be encouraged; on the contrary, the aim should be to keep that which they have made as undisturbed as possible. Continue to give fruits swelling weak supplies of manure-water when necessary, and maintain a temperature of about 70° at night, allowing it to rise 10°, or so, above that during the day. Plants, the fruit of which is just emerging from the socket, should be fully exposed to all the light possible, otherwise, the fruit will come up reluctantly, and deformed development is often the result. Subdue the aridity of the atmosphere by sprinkling the paths with water, and the surface of the plunging material in pits where no paths exist. Avoid syringing overhead. Never let the evaporating troughs become empty. If not previously done, have all fractures likely to admit drip repaired at once.—J. MUIR, *Chiswick*.

Hardy Fruit.

This is a good time to prune the hardest fruit trees in open quarters, or in orchards. One great reason for the decline of orchard fruit-culture is, the total neglect of pruning and other cultural expedients. Too often the trees are simply planted, with care or not, as it may happen, and then they are left to shift for themselves. Singularly enough, they do this as a rule, worse when the ground is laid down in Grass, than on arable land. The reason is thought to be, that the Grass always growing, impoverishes the roots by exhausting the soil over them. This view is confirmed by the fact, that the removal of the Grass has resulted in the restoration of the trees to stronger health and a higher degree of fertility. The practice of top-dressing fruit trees in Grass orchards, has also been attended with the most beneficial results. An old Devonshire orchardist once assured me that to ensure health and fertility in perpetuity, the turf over the roots of fruit trees should be taken up annually, and a top-dressing applied each second year. There can be no doubt, that it is good practice to frequently disturb the turf over the roots, and apply some fresh earth as a top dressing. I have seen the most astonishing results from the adoption of the practice with Conifers as well as fruit trees; and this is just the season to whip off the turf, apply the dressing, and replace the Grass; for the activity of root-action in November can hardly have failed to have struck most

cultivators. The activity of the healing processes extends to the tops of trees also, though not with the same energy, as in the case of the roots that are thoroughly protected by the earth, and found in a more uniform temperature; hence, this is also the best season for top pruning. As a general rule, subject to many modifications, I would counsel the cutting out of the weakest shoots chiefly. So much has been written on weakness as an aid to fertility, that cultivators have been, on that account, misled in pruning. The fertility that is born of weakness is sure to be short-lived and the produce puny. Remove the weak wood from trees, and compel the strong to bear by leaving it full length; and, if that is not sufficient, then lay the knife on the roots. And this last will force fertility. But root-pruning may easily be carried to excess, so as to cripple the vital force; which must be avoided. It is better to lead the strongest branches into fertile ways than to force them to it through root-manipulation. Either way, trees should be nourished while bearing fruit by judicious top-dressings. Prune also for fruit more even than for form. Combine both objects if possible, but if one of the two must be sacrificed let that one be form.—D. T. FISH.

Kitchen Garden.

Cauliflowers, as a rule, do not survive our winters without protection; no time should, therefore, now be lost in getting the young plants under cover. Where it is intended to winter them in frames, they should be placed on a hard bottom, such as a hard coal-ash bed, where pot-plants have stood during summer; this will help to keep the worms out of the frames, which, unless some precaution of this kind is taken, are frequently troublesome in autumn and winter. Shallow frames are better than deep ones, as they admit of the plants being close to the glass, which is a point of some importance. About 6 inches of good soil, sandy rather than adhesive, should be spread, and the plants pricked out about 4 inches apart. A few plants of the later sowing might be potted in 3-inch pots, and plunged somewhere near the glass. I like this plan of potting a part of the stock, as it enables us, if damp dull weather prevails, and if mildew is prevalent, to move the plants to a dry cool house, where, on a shelf near the glass, they soon improve amazingly; in fact, where space can be found, this is the best way of wintering Cauliflowers. A few plants might also be put out finally under hand-lights, if desired, although there is not much gained by doing this before February. The site for the hand-lights should be warm and well-sheltered, and the soil be specially prepared by digging in a quantity of good manure. A liberal dosing of soot will also be beneficial in keeping slugs at a distance, and in banishing the Cauliflower grub that is so often destructive in spring. About six plants might be planted under each light, to be finally thinned out to three, or, at the most, four in February; but, of course, the thinnings could be planted elsewhere to form a succession. In the southern and western counties, Cauliflowers may generally be safely wintered at the foot of a south wall or fence, especially if a shallow trench has been formed and the plants pricked out about 6 inches apart. When frost sets in, a row of stable litter may be placed along the front; and a few evergreen branches laid over the plants will keep all safe. As we may now shortly expect frost severe enough to injure Cauliflowers that are turning in, some means of protecting them should be at hand; the best way is, when the change of weather is apprehended—and there are always some signs by which an observant person may tell when bad weather is near at hand—to lift all that are fit for use, or nearly so, if they are large enough to be spoiled by frost; all those that are about the size of a small teacup, and that may be expected to grow a little more, should be planted close together in a deep cool pit, where they may have all the air possible without letting in rain or frost. The larger ones may be layed in thickly on some sandy bank or elevated spot in the open air, where it will be a very easy matter to keep the frost from them, by covering with straw, mats, or hurdles thatched with straw; or dry Fern would do equally well. I have often kept them in this way till after Christmas. Before lifting them—which can be best done with a steel fork—remove two or three of the bottom leaves, as they will only get broken, and tie the others loosely over the head; lift the plants with as much ball as will adhere closely to the roots, and plant them deeply, laying them in a slanting direction, with the heads to the north. Late Celery will now soon require attention in earthing up; it has grown amazingly during the last three weeks. If snails or slugs are likely to be troublesome, soot or lime should be scattered about amongst the plants and soil as the work proceeds; or, if burnt earth or ashes could be obtained in quantity sufficient for the latest crop, it would be very desirable to have it; as not only will it banish the slugs, but, being of a porous nature, the Celery will not be so liable to suffer from damp accumulating and causing premature decay.—E. HOBDAK.

Cottagers' Gardens.

The mild weather which we are now experiencing will induce late growth, not only in all green crops, but also in weeds. The latter must, therefore, be eradicated on every favourable occasion. All kinds of Broccoli, now in luxuriant growth, will be liable to suffer from the effects of frost should it set in soon; they should, therefore, be laid with their crowns to the north, a position in which they will withstand a considerable degree of cold, and in which they can be easily protected with any kind of temporary covering, in cases of very severe weather. Look over Apple, Onion, and other stores, and pick out anything that is decaying. Also see that the covering on Potato ridges effectually excludes wet. Chrysanthemums, which will now form the principal source of attraction in flower borders, should be neatly staked. Pot plants should generally be kept rather drier at the root than they hitherto have been; but, when exposed to a dry dusty atmosphere, a good washing overhead occasionally will greatly invigorate them. Calceolarias should now be potted in rich light soil; when well grown in a cool moist atmosphere, and screened from bright sunshine, they make valuable window plants. Chinese Primulas should now be coming into bloom, and, with the addition of a few berry-bearing plants, will serve to keep windows gay until the earliest bulbs are ready to succeed them.—J. G.

Evelyn's "Gardener's Calendar" for October, 1699.

To be done in the Orchard and Olitary Garden.—Trench ground for orcharding, and the kitchen garden, to lie for a winter mellowing. Plant dry trees (*i.e.*, Fruit of all sorts, Standard, Mural, or shrubs which lose their leaf; and that so soon as it falls: but be sure you chuse no Trees for the Wall of above two years Grafting at the most, sound and smooth. Now is the time for Ablaqueation, and laying bare the Roots of old unthriving, or over hasty-blooming trees. Moon now decreasing, gather Winter-fruit that remains, weather dry; take heed of bruising, lay them up clean lest they taint; cut and prune Roses yearly, reducing them to a Standard not over tall. Plant, and Plash Quick-sets. Remove Grafts after the second year, unless Dwarfs, which you may let stand 'till the third. Save, and sow all stony, and hard kernels and seeds; such as black Cherry, Morellos, black Heart, all good; Pear-plum, Peach, Almond-stones, &c. Also Nuts, Haws, Ashen, Sycomor, and Maple keys; Acorns, Beech mast, Apple, Pear, and Crab kernels, for Stocks; or you may defer it till the next Month towards the latter end, keeping them dry, and free from mustiness; remembering to cover the beds with litter. You may yet sow Genoa Lettuce which will last all the Winter, Reddish, &c. Make Winter Cider, and Perry. Towards the latter end, plant Abricots, Cherries, Plums, Vines, Winter Pears, &c.

Fruits in Prime, or yet Lasting.—*Apples*: Belle-et-Bonne, William, Costard, Lording, Parsley-apples, Pearmain, Pear-apple, Honeymeal, Apis, &c. *Pears*: The Caw-pear (baking) Greenbutter-pear, Thorn-pear, Clove-pear, Roassel-pear, Lombait-pear, Russet-pear, Saffron-pear, and some of the former Month, Violet-pear, Petworth-pear, otherwise call'd the Winter Windsor. Bullis, and divers of the September Plums and Grapes, Pines, Arbutus, &c.

To be done in the Parterre and Flower Garden.—Now your Hyacinthus Tuberosa not enduring the wet, must be set into the house, and preserved very dry till April. Continue sowing what you did in September if you please: Likewise Cypress may be sown, but take heed of the Frost: *vide Mar.* Also, You may plant some Anemonies, especially the *Tenuifolia's*, and *Ranunculus's*, in fresh, sandish earth, taken from under the turf, but lay richer mould at the bottom of the bed, which the fibres may reach, but not touch the main roots, which are to be cover'd with the natural earth two inches deep: and so soon as they appear, secure them with Mats, or dry straw, from the winds and frosts, giving them air in all benigne intervals, if possible once a day. Plant also *Ranunculus's* of Tripoly, Vernal Crocus's, &c. Remove seedling Holly-hoes, or others. Plant now your choice Tulips, &c. which you feared to interre at the beginning of September; they will be more secure, and forward enough; but plant them in natural earth somewhat impoverished with very fine sand; else they will soon lose their variegations; some more rich earth may lie at the bottom, within reach of the fibres (as above:) Now have a care your Carnations catch not too much wet; therefore retire them to covert, where they may be kept from the rain, not the air, or lay them on the sides; trimming them with fresh mould. All sorts of Bulbous roots may now also be safely buried; likewise *Iris's*, &c. You may yet sow *Alaternus*, and *Phillyrea* seeds. It will now be good to Beat, Roll, and Mow Carpet-walks, and Cammowle; for now the ground is supple, and it will even all inequalities: Finish your last Weeding, &c. Sweep, and cleanse your Walks, and all other places, from Autumnal leaves fallen, lest the Worms draw them into their holes, and foul your Gardens, &c.

THE GARDEN.

"This is an art
Which does mend nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

PRACTICAL HINTS ON NEW GROUND WORK.

THE love of change may be said to be inherent in most of us, but especially in gardeners, both amateur and professional, who, as a rule, seem to be rather sceptical concerning the poets' dogma, that "a thing of beauty is a joy for ever," and they are supported by their own garden poet, who declares that "prospects, however lovely, may be seen till half their beauty fades." There is, therefore, every excuse to be made for both employers and gardeners who, at this season, evince a desire for making alterations and improvements; and there is hardly a place where something may not be done by which its interest and beauty may be considerably enhanced. Wherever alterations are in contemplation, if a professional landscape gardener is not called in to advise, the main features of the contemplated alterations should be thoroughly considered, and a correct working plan made, before anything further is done. Improvements in small details may probably suggest themselves as the work proceeds, but nothing can be more annoying to all concerned than to find, after considerable progress has been made, that some fundamental blunder has been committed, which renders it necessary to do a good deal of the work over again. Of course, where a professional landscape gardener has been employed this rarely happens, but a vast deal of the work of this kind that is annually done is the joint production of the proprietor and his friends, with, perhaps, an occasional word of advice from his head gardener. All gardeners cannot have a knowledge of the principles of landscape gardening, and I do not know that it is necessary that they should; but, at least, all should have a knowledge of working from drawings or plans so as to be able to carry out efficiently any work of the kind that they may be called upon to execute. To a man not practically acquainted with such things it may seem a simple matter to alter certain ground levels and turf them over; but this is a kind of work that calls for a considerable amount of practical knowledge, seldom possessed without a certain amount of special training, if it is expected to stand for years unimpaired. In the first place, in laying down designs or making alterations in the lie of the ground, no man should trust to the eye alone, however true it may be; on the contrary, everything should be rigidly carried out by tape and level; and good stout stumps, that cannot easily be moved, should be driven in at short intervals, so that the straight edge will easily reach from one line of stumps to another throughout the whole extent of the ground operations. And not only should this be done in geometrical gardening, but also as far as possible in the more picturesque portions of the grounds where graceful, easy-flowing undulations are admissible, for the best design may be marred by bad workmanship in carrying it out. In laying down new turf, it is most important to see that the ground has been properly prepared; where it has to be raised or made up, see that it is well rammed as the work goes on; if this is neglected, it eventually settles into holes and hills, before many years are passed, that will cost far more to put right than it would have done to execute the work well at once. It may be added, that imperfectly done work never looks well even at the outset; and these earth settlements may go on for years, and the turf have to be taken up time after time, and all for want of a little more care and labour being bestowed upon it in the first instance. In laying down turf, much time and labour will be saved if the turfs are all cut exactly of the same size. The best way of securing this is to have boards made one inch thick and the required size—say, about 3 feet long and 1 wide. Where the turf is good and tough, a man may take one of those boards, lay it flat on the Grass, and cut all round it; he then moves his board and cuts again, and so on, taking care to stand on the board while he is cutting, which will keep it in its true position. This is a far quicker and better method than cutting by the line; for no man, however careful, can cut his turves all the same width by the line alone; and the time lost

in laying turves of irregular sizes would be considerable; while any man that had never handled a tool before, could cut close to a board. In altering ground-levels where the sub-soil is bad, the surface-soil should be taken off and reserved to go on the surface again. If turf is expected to maintain its colour in dry seasons, a good depth of soil is absolutely necessary, and, especially so, in the case of terraces and slopes that are much exposed to the sun. In making new gardens, if good turf can be easily obtained, it will be found to answer far more satisfactorily than sowing Grass seeds, even when the additional cost is considered; but in cases where it may be necessary to depend in the main upon seeds, all the more prominent points, such as edgings, &c., should be turfed. There is a mode of turfing by what is termed inoculation, which I have sometimes seen practised. It consists in laying down small bits of turf at short intervals, with the view of their uniting and making a close sward. This plan, however, is at best, but a makeshift, and should be adopted only as a last resource; and be helped, moreover, with a top dressing in spring, supplemented, if necessary, by scattering a few seeds of the finer Grasses over it. The most satisfactory example of inoculation I have yet witnessed, was performed in the following manner:—The available turf was collected into convenient heaps and chopped up into very small bits and scattered evenly over the whole surface, and then thoroughly rolled down, the rolling being repeated as often as necessary. This was in the month of March, and, showery weather following, the bits of Grass grew rapidly, and, in a short time, made a fine piece of lawn; but, wherever this plan is adopted, the turf so created must have time to establish itself thoroughly before either scythe or mowing machine are put to work upon it. One word may be advisable as to the management of men employed to carry out work of this kind. I have found it best to take them, as it were, into my confidence, and let them understand the methods I intend to adopt in carrying out the work, and the result I wish to effect, so that they may thoroughly understand all about it. There is a good deal of force in the proverb, "He who hesitates is lost," and there is no question that a hesitating manner in dealing with workmen, or doing the work piecemeal, as it were, has a depressing influence upon those employed, that is, "if they are worth their salt." E. HOBDAY.

The Gardens of the Hesperides.—In this age of general research, every day, so to speak, is bringing to light facts which go far to prove that all the legends and fables of the ancient world had their origin in solid realities, and that all the gilding of poets, and all the wild superstitions of historians have not rendered these realities unrecognisable, when modern research has signalled their discovery. The beautiful legend concerning the three daughters of the evening star Hespera, who dwelt in a lovely hidden garden near the northern coast of Africa, in which the melodious accent of their songs was heard, though the singers were never seen, on account of the lofty wall of rocks piled by the gods, which surrounded the garden, is founded on very simple facts, as regards the garden itself. Even the golden fruits, and the dragon Ladon who, issuing from his dark cave, guarded its entrance, have their foundation in fact—the embellishments of the poetic legend, regarding both golden fruit and dragon, being faithful picturings, very little more highly coloured than those of modern poets. The lovely garden valley, watered by many streams, and near which the great city of Berenice arose afterwards under the Egyptian rule of the Ptolomies, still exists in all its primeval beauty. The fabulous reek-piled walls are, the great mountain cleft, in which lies, softly sheltered, a deeply depressed winding valley, full of the richest vegetation at all seasons, its golden fruits being those of Orange and Lemon trees, which bear both flowers and fruit all the year round. The dragon, is neither more nor less than the tortuously winding stream, issuing from a cave, which crosses the entrance of the valley, and seems to prevent all access to its picturesque recesses. Now, that more than usual attention has been called to the real existence of the garden of the Hesperides, in consequence of the village of Bengazi, which occupies the site of the ancient Berenice, having been signalled as one of the secret seats of the slave dealers (whose proceedings are about to be suppressed), we shall, doubtless, have the ever enterprising Mr. Cook conducting his Egyptian tourists to the spot, by a small detour, at so much a head; and the gardens of "The Hesperides" will go down in his list of stations for so many hours, or days, halt, as may be found convenient; all for a very moderate extra charge of so many piastres.

NOTES OF THE WEEK.

— AMERICAN Apples of the past season's growth are now selling at moderate rates in provincial towns, both in England and Ireland. The highly coloured and well-flavoured Baldwin is the commonest kind as yet. As usual, they come in barrels without any kind of packing material, and come, as a rule, in excellent condition. That Apples should be sent several thousand miles, and then be sold as cheaply as home-grown fruit, is a noteworthy fact. At this rate of progress, fruitless and cold regions will soon be supplied with the finest fruits at a cost that places them within the reach of all classes.

— THE appearance of the Phylloxera in Austria has been announced in the *Official Journal* in the following passage:—"One of the Vines of the central establishment, created in Lower Austria for the culture of fruit-bearing trees, has been found to be affected by Phylloxera, which had evidently been imported with Vine plants received from America in 1859." All the Vines of that kind will therefore be immediately destroyed; and the authorities are taking every precaution in their power to prevent an extension of the evil.

— At the late Lyons horticultural exhibition, the new and fine-looking seedling Pear, Abbé Pétel, a Calebasse, excited general attention; but, owing to the present exceptional season having matured many kinds of Pears before their usual period of ripening, thus, in all probability, depriving them of their special qualities both as to flavor and keeping, many connoisseurs have been induced to withhold, for the present, their final judgment as regards the merits of this promising new Pear.

— CATTLEYA GIGAS has just flowered in Lord Londesborough's collection at Norbiton. It is one of the best of the many forms which all more or less resemble the true old *C. labiata*, one of the rarest of all the Cattleyas. The true form is, however, bearing fifteen flowers on three spikes, in the above collection, and is certainly a noble object, the flowers being nearly 9 inches across, and of a rich lilac colour, beautifully veined and frilled. The lip is stained with crimson-purple, suffused with gold and delicately veined. A pure white form of the *Odontoglossum Roezlii*, is also in bloom in the same collection, and is characterised by great breadth both of leaves and segments of the flowers.

— MESSRS. VEITCH'S nursery, at Chelsea, is at present well worth a visit, the Pitcher plants there being just now in splendid condition, and the show of Chrysanthemums strikingly brilliant. Prominent among them were the following, viz.:—*Elaine*, pure white; *Beverley*, also a fine white; *Golden Beverley*, rich yellow; *Aureum multiflorum*, soft golden-yellow, distinct and fine; *Empress of India*, still one of the finest whites; and *Jardin des Plantes*, unsurpassed among yellows. One of the best rosy-lilac show kinds is *Princess of Wales*; and *Venus* is also good. Amongst the Japanese forms, *Fair Maid of Guernsey* has flowers fully 7 or 8 inches in diameter. The Pine-apple Place Nurseries, Maid Vale, are also now gay with Chrysanthemums, and well worth a visit; as also the fine collections of these plants at Messrs. Dixon's, Amhurst Road, Hackney, and Messrs. Cutbush's, at Highgate. Chrysanthemums, indeed, are at present everywhere unusually brilliant.

— WHETHER or not the visitors to the Brighton Aquarium go there with any idea of becoming more intimately acquainted with the wonders of the deep or not, there is no doubt that an exhibition of ocean plants would be, at least, as popular as one of fish. A sea-weed, in a growing state in its native element, is very different from sea-weed cast up on the shore, and a careful selection and arrangement of growing specimens would greatly enhance the interest of the tanks. We may supplement these remarks from *Nature* with a suggestion, that an aquarium, constructed expressly for sea-weeds alone—a kind of "ocean garden"—might in itself form a very popular and interesting exhibition, if sufficiently extensive, and containing a vast collection of marine algae from all parts of the world, many of which are grand as well as beautiful examples of vegetation.

— Now, when we have little in bloom in outdoor borders except Chrysanthemums, an enumeration of a few of the best Michaelmas Daisies or hardy Asters in flower at Kew may not be uninteresting. Foremost among them may be named *A. grandiflorus*, a fine kind more thickly studded with large purplish-blue coloured flowers than we have ever before seen it in an open bed. *A. paniculatus* is also now in great beauty; it attains a height of about 5 feet, is profusely studded with good-sized pale lilac-blue flowers, and forms a fitting associate for such kinds as *penulans* and *Novæ Angliæ pulchellus*, of which there are also now good examples in flower at Kew. The dwarf Aster *versicolor* is likewise still blooming profusely in beds, where it will doubtless continue in beauty for some time yet to come. Of other plants in bloom the most striking are *Tricyrtis hirta*, which, on a sheltered border, has grown luxuriantly during the past season and is now

bearing its peculiar-looking spotted flowers in tolerable abundance; *Ophiopogon spicatus*, a tuft of which is thickly covered with spikes of lilac-coloured blooms is likewise very pretty.

— THE Cryptogamic herbarium of Mr. T. Carroll, of Cork, rich in Irish Lichens, and containing many of the late Admiral Jones's specimens, has been acquired by the British Museum.

— A work on St. Helena and its products, by Mr. J. C. Mellis (near completion), is to contain a complete flora of that island, illustrated by coloured plates, which will include several of the now almost extinct Arborescent Compositæ.

— M. F. GAILLARD, of Bregnaix, sent to the exhibition, instituted by the Association Horticole Lyonnaise, a magnificent collection of 160 distinct varieties of choice Grapes—an interesting and instructive display such as is seldom met with.

— THE new variety of the Burnet Rose, discovered by Mr. J. M. Webb, in 1873, in hedges near Hoyleake, in Cheshire, is, we believe, to be named *Rosa involuta* Webbii. It is a distinct and pretty variety, well worth the attention of lovers of the better kinds of English wild Roses.

— THE exhibition of Fungi, at Munich, which was held last month in the Crystal Palace, proved a great success. The arrangements and classification were exceedingly good, the edible kinds being clearly indicated. It is said that over 10,000 persons visited the exhibition, though it was only kept open eight days.

— DURING an excursion of the Scottish Botanical Alpine Club, in August last, to the Aberdeen and Forfarshire Mountains, Mr. John Sadler discovered a singular Alpine Willow, which will be named *Salix Sadleri*. It is to be fully described and figured in the forthcoming journal of the Edinburgh Botanical Society.

— THE new seedling Strawberry raised by Mr. Corbin, head gardener to the Marquis of Mortemart, at Lachassagne, has been pronounced, by a horticultural commissioner sent to examine it in a growing state, to be the best variety yet produced. Notwithstanding the advanced season, the plants were found still covered with both fruit and flowers. It is said to be a kind well-suited for forcing.

— THE ground cultivated by market gardeners in and around Paris amounts to over 3,000 acres. It is stated that 360,000 glazed frames, and more than 2,000,000 cloches are employed in the production of vegetables alone. The annual amount expended for manure is said to be £72,400, and the total receipts from the sale of vegetables and other productions of the market gardens to exceed half a million sterling—a sum probably much under the mark.

— LOVERS of wall plants, particularly those who reside in the milder parts of the kingdom, should not overlook *Solanum jasminoides*, a plant well suited for such positions, and one which possesses the good property of being a continuous bloomer. A plant of it, occupying a wall pillar in the Royal Gardens, at Kew, was in bloom as long ago as June last; a condition in which it has remained throughout the summer and autumn months, and even now it is literally covered with blossom.

— AN international exhibition of fruit is announced to take place at Amsterdam in 1875, when a general pomological congress is to be convened. The names of the gentlemen of the commission of general management, comprising those of some of the most eminent of the Dutch horticulturists, is a sufficient guarantee that the arrangements will be judicious and complete. It is intended that the congress should occupy itself very specially with the nomenclature of fruit-bearing trees and shrubs.

— THE doctrine (says *Nature*) that the conspicuous colours of flowers are entirely due to the necessity for cross-fertilisation by the agency of insects seems to be taking the world by storm. It is supported by Mr. Darwin and Sir John Lubbock. It could scarcely be put forward on better authority. Yet there are several facts with which it does not harmonise. For instance: 1. Cultivation increases the size and colour of flowers quite independently of the existence or non-existence of insects.—2. Double flowers in which the doubling arises from metamorphosis of stamens or pistils are more showy than the single forms, yet insects can be of little use to them, since they are either partially or entirely barren. The double-blossomed Cherry is brilliantly conspicuous, but it bears no fruit.—3. Such abortive flowers as the cultivated Gelder Rose and *Hydrangea* depend for their beauty upon the destruction of the reproductive organs. If their increased splendour is meant only as a lure to insects, it is surely an absurd failure.—4. The autumn colours of leaves and fruits can serve no such purpose, yet these are often as bright and conspicuous as the flowers of summer.—5. Fungi and Lichens exhibit brilliant colours, which can have nothing to do with insect-fertilisation. Do not these facts indicate that though insects may be attracted by conspicuous colours, and may have some influence in the maintenance of coloured species, there is yet a deeper and more permanent cause for the colour itself?

THE FLOWER GARDEN.

THE SNOW PLANT.

IN reply to "Q.'s" enquiry (see p. 416), I beg to say that this plant is figured and described in Torrey's "*Plantæ Fremontianæ*," under the name of *Sarcodes sanguinea*. I first saw it in June at Truckee, which is the chief lumber station and entrepôt of the Nevada Mountains, where they are crossed by the Central Pacific Railway. As the train was slowly starting into motion from this station, my eye caught a man standing on the platform with a magnificent deep red flower in his hand—large enough to form a nosegay in itself—rich in colour and striking in appearance. I knew in a moment that it was the Snow flower; but, before I could signal the man to approach, we steamed away, and the Snow flower vanished from my sight. A fortnight later I was again at Truckee, and this time independent of railway trains. I was one of a small party who had come for a ten days' expedition through the neighbourhood, one or two of us to visit mines, and others, like myself, to see everything that could be seen, especially the magnificent forests of Pines, which surround Truckee on every side. We spent several days in driving, from morning to night through the never-ending leafy forest of gigantic Pines, but, as the days slipped by without ever meeting with the Snow plant, I began to fear that we were now too late for it, but, on the very last day, as we were returning to Truckee, we came upon it. We were crossing a ridge very high up, and our way laid over a shallow hollow between two crests on each side of us. The snow was lying in large patches, and completely filled up this hollow. The ground was wooded with Pines, but not thickly covered. Open spaces of no great size allowed the eye to penetrate for a short distance, and near the bottom of the hollow I descried a solitary spike of the Snow plant growing erectly out of the snow. I was out of our conveyance in a moment, and secured my prize; but I could not keep my friends waiting for an unlimited time to get it up by the root, and my experience with other reputed parasites that grow on roots had taught me that any examination of roots in that direction requires great care, plenty of time, and proper appliances, none of which I had to give. Two or three other specimens were found growing at no great distance. I brought one with me to San Francisco, where I found it to live in water for several days. From its texture, I should expect it, under its natural condition, to flower for a long time. It has something of the habit and appearance of a closely-packed gigantic Hyacinth, with a stem about the thickness of a Cabbage-stalk, the leaves and flowers closely adpressed to it, and all blood-red. The kind of plants that it most brought to my mind were some of the Bromeliaceæ, like *Billbergia* with coloured leaves; not that it has any actual affinity to them, but the flowers, and especially the calyx, are like those of that class of plant; the stem and leaves, however, are of the same kind of fleshy consistence as Cabbages. It belongs to the order, or I should prefer to say the family, Monotropaceæ, which consist of parasites, said to grow on the roots of Pine trees. Whether this is true or not, and, if sometimes true, whether it is not an accidental growth through a half-decayed root, has been doubted by some. The best known species on the Continent is *Monotropa Hypopitys*, which occurs in Germany, and from which a powder is made which is said to be good for coughs in sheep. The *Sarcodes sanguinea* has no smell, but some allied species are said to have the odour of Pinks and Violets. The family of Monotropaceæ is composed of five genera and seven species, and four of these genera and five of the species are peculiar to North America.

ANDREW MURRAY.

CLEMATIS ÆTHUSÆFOLIA.

THIS pretty Clematis, of unusual character, forms a very graceful and desirable addition to the already well-known species of that beautiful family of plants. Its foliage, which is extremely elegant, resembles much more closely that of the genus *Æthusa*, or Fool's Parsley, than that of any of the family to which it belongs; from which resemblance the plant has received its specific name. The stems are delicately slender, and the plant, rising very elegantly, attains a height of 6 to 7 feet. The Campanula-shaped flowers are produced in great abundance, and are of a yellowish cream-colour. Their elongated tube recurves itself at the opening in four petals, and their drooping habit has a very pleasing effect, especially when the plant is in its season of full bloom; at which time a crowd of these drooping flowers, all open at the same time, issue at close intervals from every leading stem for 3 or 4 feet, looking like a shower of pale fire from a falling rocket; the effect of which is exceedingly charming. It is not known from whence the plant was originally received; but the seeds from which it has been raised were sent from Naples. This pretty species of Clematis flowers in August and September.

Fool's Parsley-leaved Clematis (*C. æthusaefolia*).

CROWN IMPERIALS.

THAT old inhabitant of our gardens, the Crown Imperial, is very seldom mentioned in our floricultural publications, yet it may be very appropriately classed among those worthy old garden plants that are just now somewhat neglected. There are handsome showy varieties of it, both double and single; but they are not nearly so much appreciated as they deserve to be, and are seldom planted in newly-formed gardens, though they are still found in old cottage gardens in all the glory of their vernal brightness, decked with their coronets of red, orange, or yellow flowers. Many old and well-known herbaceous plants bid fair to come to the fore once more, and it maybe there is a good future in store for the Crown Imperial. It is not necessary to enumerate the names of the assumed varieties; suffice it to state that, as far as real points of difference are concerned, they may be summed up in the single red and the single yellow, with the large flowering forms of these two, and the double red and double yellow varieties. For decorative effect the single flowers are certainly to be preferred to the double ones; though the last-named are much dearer and scarcer; for it would seem that the double flowers frequently run back to the single form. The flowers of the Maxima red and Maxima yellow, as the large-flowering varieties are designated by the Dutch growers, are nearly half as large again as the ordinary single flowers, and this not the result of a higher cultivation or a stronger development, but an abiding characteristic of the plants. The Crown Imperial may be grown and flowered in any loamy soil forming a flower border; but to do it full justice, and to ensure a fine head of bloom, it should be planted in a deep rich soil, well drained. If the soil is not rich, it must be made so by the addition of a good dressing of well-decomposed manure. The stems send out, just above the bulbs, a large number of young strong roots. At that stage of their growth, the plants will be benefited by a top dressing of decayed dung placed close to the stems; in fact, a good coating of manure of this kind can be laid about the plants during the winter, as it will give them a little protection during severe frosts. The Crown Imperial is one of those plants that, when once planted, requires to be let alone and remain undisturbed for years. Strong bulbs do not always flower the first year after planting; they appear to require to get thoroughly hold of the soil, and then the succeeding year they throw up strong

flower-spikes, crowned with their showy circlets of pendent bell-shaped blossoms. The Dutch bulb-lists name one assumed variety that has been named the Crown-on-crown Crown Imperial, on account of its tendency to produce a double ring of flowers one above the other. It would appear that it is necessary this variety should be well established and nourished, or it will not preserve this double-crowned form. It may be described as a double type of the single red variety. There are also two variegated forms, one having the green leaves margined at the sides with silver, the other with gold. Both of these are really effective out-door plants in the spring; but, to give due effect to the leaf-marking, they should be grown in clumps of several bulbs. Both of these bear red-coloured single flowers. It was an article of belief with some of our old gardeners that, if the leaf-stem of the Crown Imperial is not allowed to decay naturally, on the bulb from which it springs, the bulbs will rarely produce a successional one strong enough to bear a crown of flowers the following season; and modern practice goes to recommend that the dying flowers may be removed; while the stem, which would appear to exercise some influence on the perfect maturation of the bulbs, should be left to fall away by a process of gradual decay. R. D.

FINE VARIETIES OF AMARANTUS.

You have alluded (see p. 311) to the fine effect produced at this late period of the season by means of masses of Love-lies-bleeding, Prince's Feather, and other well-known kinds of *Amarantus*. The effect produced by these fine old garden favourites in large masses is, no doubt, very striking; but there are more recent varieties so far more splendid, that I unhesitatingly recommend the managers of the floral displays of Hyde Park and Kensington Gardens to avail themselves of them next season. The first to be named is the scarlet-leaved weeping *Amaranth*, the *Amarante melancholique* of French gardens. The whole of the leaves and stalks of this variety are of the richest crimson-scarlet, so that the plant becomes highly ornamental as soon as the first leaves are developed. Masses of this plant may be made to produce a strikingly beautiful contrast with such as have foliage of a light vivid green, with white or yellow flowers; or, in short, with any plants in which bright green tints predominate. In such situations, it may fitly replace the handsome *Coleus Verschaffelti*, which requires the heat of a stove to bring it forward. The seeds may be sown in an open border, or, where fine early plants are required for bedding purposes, they should be sown upon a partially-exhausted hot-bed in March or April, and planted out in May. Another variety, called *A. bicolor* by seedsmen, has the under part of the leaves cool crimson, while the upper surfaces are of a warm glowing carmine of very striking character, which, at a short distance, produces the effect of splendid flowers. A third grand variety, known as *A. tricolor*, produces an effect of a very different but equally splendid character. The leaves of this finely variegated plant are alternately red, green, or yellow, while many are beautifully marked with all three colours. It is a truly ornamental plant in the strongest acceptation of the term, and, when finely grown, must charm all who see it. While so many costly novelties are run after with such avidity, it may be well to try back occasionally, and expend a few pence upon some seed-packets of recently improved varieties of *Amarantus*, although they may not be novelties of the current, or even the last, season. AMARANTH.

Cypripedium spectabile.—Usually Orchids are connected with hothouses and steaming vapour; but several of them come from temperate regions, and many of them are perfectly hardy. In the last class none equals in beauty the noble *C. spectabile*, a native of low meadows and bogs in North America from Canada to Carolina, chiefly in mountainous districts. Many of its congeners from warmer climates, which are to be seen in our stoves and Orchid-houses, do not equal this in beauty of colour, the large and much-inflated white lip being so beautifully stained with rosy-purple. It is as hardy as the common Dock, and every person interested in hardy flowers should endeavour to establish it. Occasionally, it is grown in pots or pans in Orchid-houses; but for this course there is no necessity. We have seen it attain a height of nearly 3 feet when planted on the north side of one of the ranges of glass in the Botanic Gardens at Glasnevin. The conditions essential to its perfect health in the open garden are, a deep peaty or other vegetable soil, and a sheltered and somewhat shaded position. In this country, the slight shelter is of more importance than the shade; strong healthy plants to begin with and moist vegetable earth not less than 2 feet deep, are more important than either. In very dry districts, it would be desirable to place the plant behind a north wall; but there can be no doubt that if the other conditions were secured, it would thrive in sheltered

borders, or on the margins of beds of shrubs. Wherever there is any kind of bold or diversified rock-garden, this should be placed on its lower flanks, in different positions and aspects, and nothing would be more strikingly beautiful and novel, than one or two isolated tufts of it on the margin of a select plantation of shrubs in the pleasure ground.

Ivy on Cemented Walls.—Let me advise "R. A." Workington, Cumberland, not to put either cement or rough cast on his house if he really wishes to clothe it with Ivy. For the last eight or nine years I have been trying to cover my house in this way, and though the Ivy has a rich border, and grows luxuriantly, it refuses to cling to the cement firmly, and each storm tears a large portion of it down. It does somewhat better on the rough cast, but neither suit it as well as stone or brick, and if your correspondent leaves his house exactly as it is, though it may appear unsightly at first, he will be repaid by the quick growth and tenacious grip of the Ivy on the walls. If he further adds a plant here and there of the beautiful *Ampelopsis Veitchii* (or Veitch's Virginian Creeper), he will be repaid by its glorious tint in the autumn, which it maintains long after the common Virginian Creeper has faded, and littered the ground with dead leaves. This small-leaved *Ampelopsis* has the same dislike to lime as the Ivy, and I cannot get it to cling well to my rough cast without an occasional nail, a support which it would scorn on either brick or stone.—J. H. W. T., *Belmont, Carlisle*.

The Shamrock Pea (*Parochetus communis*).—Among rock and border plants, none are more worthy of culture than this. It has the leaf and habit of the common Shamrock (*i.e.*, a concise form of *Trifolium repens*), and from amid its leaves and little runners solitary blooms rise erectly, supported on stems; about 2 inches high, each flower like a handsome blue Pea. A plant so beautiful and distinct will be very welcome in the rock garden or in a choice border of early flowers. It thrives freely in fine sandy loam, with plenty of peat and leaf mould, in a well drained spot. It is suited for association with the choicest and most diminutive Alpine flowers, and when placed on the rock-work, should be somewhere near the eye, as it is not of a conspicuous order of beauty, nor of a vigorous habit out of doors. I first met with this plant in the Edinburgh Botanic Garden, where it was well grown in pots as a frame plant by Mr. McNab; and so treated, it grows much more freely than in the open air, drooping well down over the edges of pots or baskets, and running about as freely as a soft "Creeper" when planted out in the soil of a cold frame or on a light bed in an orchard house. It has, however, been proved to be quite hardy at Glasnevin.—W.

A Golden-leaved Plant.—The plant we allude to is, like the *Pyræthrum*, one of the Composite; but is unlike it, in being of a shrubby character. It is the Golden-leaved *Diplopappus*, *D. chrysophylla*, a hardy, low-growing shrub, which may be popularly described as Heath-like in appearance and foliage, with the exception that the *Diplopappus* looks as though it had been dipped bodily into a solution of gamboge or other rich yellow pigment; in fact, it is the most perfectly gold-coloured plant that has ever come under our notice. It is perennial, perfectly hardy, will strike freely from cuttings, and accommodate itself, we should say, to any requirement, whether an edging or belt of gold to the flower bed, or a veritable obelisk or pillar of gold, should fancy so choose to fashion it. Apart altogether from bedding or flower ground considerations, grown in its natural form as a shrub it is well calculated to arrest attention, and deserves to be brought under notice.—*Irish Farmers' Gazette*.

Culture of the Chrysanthemum.—Although the Chrysanthemum receives a good share of attention in most gardens, we rarely meet with what may be termed creditable specimens of it—*i.e.*, plants with good foliage as well as flowers. By the time they come into flower, they are mostly naked for a foot or more above the pot, and, in order to show them off to advantage, other plants have to be set in front of them. To obviate this, strike the cuttings in April, or as soon as they can be obtained, under a hand-light out of doors; and, as soon as they are nicely rooted, plant them carefully on a border previously prepared for their reception, 2½ feet apart every way—a distance which allows them plenty of room, and sunlight free play among them—a condition most essential as regards securing strong sturdy plants. After they have been planted and watered, I give the border a good top-dressing of rotten manure; I prefer this to digging manure in when the ground is prepared for them, as, being surface-rooting plants, they feel the benefit of it almost at once, and it also prevents the soil from cracking or becoming parched. I keep them well stopped until the last week in July, when stopping is discontinued, and all the attention they afterwards receive is an occasional sprinkle overhead in the evening until they are taken up and potted. About the second week in September, or as soon as they show flower, I take them up as carefully as possible, and pot them in rather small pots (large ones being unsightly), using rather a rich compost. They are then placed in a somewhat shady position until they have become

established, when they are fully exposed to sunlight. I need say nothing about training, because that is an easy matter, but the sooner they are prevented from rocking about and becoming broken by the wind the better. Weak manure-water at every watering, is of great service to them, until the flowers begin to expand, when it should be discontinued. We grow a great many Chrysanthemums here; and, during the past summer, the advantage of planting them out has been fully proved, obviating, as it does, the labour of watering, shifting, and plunging, which is considerable, when they are grown in pots. My plants, treated in the way just described, are about 2 to 2½ feet in diameter, with ample leafage down to the pots, and some of the Pompones are now literally solid masses of bloom.—J. PREWITT, *Stowe Gardens, Buckingham.*

A WINTER-FLOWERING CLEMATIS.

(C. CIRRHOSA.)

This peculiar and valuable plant is too little known and planted. It is quite hardy and vigorous in growth, and bears a profusion of bloom throughout the winter and spring. We first noticed the plant at Glasnevin, and Dr. Moore writes to us:—"I consider it one of the very finest winter-flowering climbing plants that we have in cultiva-

Clematis cirrhosa.

tion. It is half-evergreen, and continues in leaf and flower from the end of November till February." At Glasnevin, the most effective specimen formed a dense isolated mass, but it is well suited for covering walls, bowers, root-work, &c. To encourage its winter-flowering habit, it would in all cases, be desirable to give it a sunny sheltered position.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Pansy Miss Maitland.—I am sorry that "A. D." (see p. 359) is dissatisfied with Miss Maitland. I have seen it grown in many different places, and its appearance has ever impressed me that it is one of the finest whites extant. It was raised at Eccles, in Dumfriesshire, by a Mr. Ross, who, when alive, was very proud of this seedling.—J. M. C.

The Tree Medick (*Medicago arborea*).—This plant at first sight reminds one of *Coronilla glauca*, but it has larger foliage of a fresher green colour. It forms a low bushy shrub, and is now flowering on a south wall at Kew. Its flowers are bright orange in colour and very ornamental.

***Yucca draconis*.**—This is a robust broad-leaved species, and is now flowering in the succulent house at Kew. The leaves are broadly sword-shaped, and of a pale green colour—not glaucous, as in most other species. The flowers have rather long petals, and are of a pure white colour and of very ornamental appearance.

Garden Roses and Human Hair.—I have been informed that human hair is now used in the cultivation of Roses. Can any of the readers of THE GARDEN tell me if they have tried it, and, if so, what soil it is the most suitable for.—A. W. [S. R. H. replies that he knows something of the converse of this theory, i.e., of the application of Roses in the cultivation of human hair, having largely used "Rose oil" in his youth, and believing that when Leech's hair-cutter compared the perfume of a Bean-field to "the most delicious 'air oil,'" that particular oil was in his thoughts; he also desires to express his admiration of Roses (not artificial) as ornaments of the hair, and is not at all surprised that she who wore a wreath of them made such a profound impression upon the gentleman, who sang her praises that night when first they met; but he has no experience of the influence of ringlets upon roots (whether ebony locks would darken, or curls, which vulgar little boys call carrots, would brighten the complexion of the Rose), having only torn his hair, metaphorically, in the Rosarium, when frost or Fungus have destroyed his hopes.]

THE ARBORETUM.

BEST CYPRESSES FOR BRITAIN.

SPECIALISTS are all familiar with applications for information in their particular department. One kind that very often reaches us, and, no doubt, also other editors of gardening periodicals, is for information as to the different kinds of plants that ought to be planted under specified circumstances. One man is making a Rose garden, and wants to know the names of the best twenty-four Roses; another has a similar demand for Ferns; another for Pines, Maples, Cupresses, and so on. What is wanted by one man who takes the trouble to write is, no doubt, desired by a dozen who do not; so we have thought it may be convenient for some of our readers if we reply in our columns to such applications somewhat amply. The following is our reply to a correspondent who consults us as to the best Cupresses:—

Cupressus Lawsoniana.

We think *Cupressus*—or, to speak more definitely, *Chamaecyparis*—*Lawsoniana* the finest introduction belonging to the Cypress group that has ever been made into this country, and, consequently, the finest Cypress that exists in it. We do not say that it is finer in California than the *Wellingtonia* or *Libocedrus decurrens*, or *Cupressus Lambertiana*. We are speaking only of them from the planter's point of view in Britain. We admire it for the beauty of its form and its departure from the strict *Arbor-vita* shape into that of a tree, and a tree with a handsome well-defined character. We admire the richness of its foliage; are thankful for the rapidity of its growth; anticipate a fine quality of timber, judging from that of the tree in Oregon; and are charmed with the gaiety of its male flowers and the rich clusters of its small irregularly formed fruit. The character of growth and habit of the tree are constant. See one, see all. You can never mistake it, but its foliage is as inconstant; and if one has a choice in colours (as every one has), it is just as necessary in giving an order for plants that you specify the colour as even the kind of tree you want. A friend of ours who was greatly taken with a beautiful fine-growing *Lawsoniana* of the deepest glaucous green, turned up with silver, inquired its name, and ordered a quantity of plants, determined that his place, too, should rejoice in a like loveliness, but afterwards complained that what he got did not look like the same tree. He had got ordinary light-coloured plants. Therefore, if you want your trees to be deep in colour, glaucous, and silvery, you had better say so in your order, or, better still, pick your plants yourself. Another thing in which one may be disappointed is the colour of the male flower. When the plant was first introduced, it was not known that it had the recommendation of having a showy male flower. As the reader knows, the ordinary colour of the male flower of Cupresses is yellowish-fawn, noways conspicuous and noways remarkable for beauty, but the flower of *Lawsoniana* is brilliant crimson-scarlet, as the colour of a soldier's coat, with a slight shade of crimson in it. It first flowered in this country when Lord Palmerston was paying a visit to Edinburgh. Old Mr. Charles Lawson was then Lord Provost of Edinburgh, and naturally the Prime Minister honoured the chief magistrate by paying a visit to his nurseries. The Lawsons had the first plant of *Lawsoniana* raised in this country; and it so happened that, just at that time, it first put out its scarlet bloom; which pleased Lord Palmerston, who had a fine taste for the beautiful, and delighted Mr. Lawson, as it revealed another excellence in his favourite Cypress; but, as we have just said, this is not to be depended upon. Some years after *C. Lawsoniana* had been described, another species was described by Professor Kellogg, of San Francisco, under the name of *C. fragrans*. It was introduced into this country, and botanists could see no difference between it and *Lawsoniana*. It was said to have fragrance, or, at least, more fragrance than *Lawsoniana*; but no difference, in this respect, was perceptible in this country, and so it rested as a doubtful species until it flowered (in the garden of Mr. Isaac Anderson Henry), when it was found to have a yellow flower instead of a red one. This was pounced upon as a specific character distinguishing the two; but it has not proved to be so. Further experience has since taught us

that the flower differs in colour, as much as the foliage does, in different individuals. From the same seed-bed we get yellow, scarlet, and purple male flowers; so fragrans must be withdrawn as a species. The wood is so fine, that a slab (of the so-called fragrans) was exhibited at San Francisco for its beauty. It is a narrow-growing tree, and so is well adapted for places where room is deficient.

Chamaecyparis obtusa, pisifera, &c.

Two or three allies of *Lawsoniana* have been introduced from Japan under the generic name of *Retinospora*. These are all of the same class as *Lawsoniana*. They are very promising; but have not yet made sufficient progress in this country to allow us to place them in the same rank as *Lawsoniana*.

Chamaecyparis nutkensis.

Another species from the northern parts of north-west America, called *Chamaecyparis nutkensis*, but better known to horticulturists by the name *Thujopsis borealis*, under which it was generally known at first, stands very near *C. Lawsoniana* in beauty and value—many people rank it higher. It shows less variety in the colour of its foliage, and is darker and dingier. The accounts we hear of it from its native country speak of it less favourably than we should expect from its appearance here.

Thuja gigantea.

We have already repeatedly had occasion in these pages to speak of this species in terms of the highest appreciation. For rapidity of growth, it is, probably, even in advance of *Lawsoniana*, and its colour being of a light lively green, contrasts well with it. It is one of the chief *Cypresses* of the future.

Libocedrus deccurrens.

If this will only thrive in this country, it may come near to supply the place of *Wellingtonia gigantea*, should the latter prove unsuited to it. They grow in the same forests, and are both giants, surpassing all around; the colour of their bark is the same, the style of buttresses which surround the trunk is the same. The upper part of the trees differ however; *Libocedrus* has its branches disposed all around the stem like the branches of a candelabrum, which is particularly well seen when the tree is dead. The then bare sticks appear standing up all around the stem, like branches of a candlestick. The disposition of the branches in *Wellingtonia* is quite different—short stumpy arms, generally clustered near the top of the tree.

Cupressus macrocarpa.

Those who were familiar with the Royal Horticultural Society's Garden at South Kensington for a few years after its formation, will remember with regret two magnificent plants of *Cupressus macrocarpa* which stood immediately under the terraces, one on each side of the water-fall. These had been brought from Chiswick, and were understood to be the original plants raised from seed sent home to the Horticultural Society by their collector, Mr. Hartweg, in 1847. For a year or two they were one of the chief beauties in the way of plants that were to be seen in the garden. Then they got darker in colour, and less healthy in their appearance; their foliage lost its denseness, the branches got scraggy, and finally they disappeared. It was the town soot that killed them; or at least so enfeebled them that they fell easy victims to the first untoward circumstances with which they had to contend. But these were by no means the only fine specimens of this magnificent tree which, at that time, might be seen in the neighbourhood of London. At Kew there were splendid examples, and everywhere this *Cypress* grew with a luxuriance and a beauty that seemed to indicate that it was perfectly suited to our climate. It had stood with little damage the cold of 1860-61, the severest winter that has been felt by this generation; and yet where are all our fine specimens of it now? Gone—swept away by the winter of 1866. No! not *all* gone, but nine-tenths at least are gone, and where the sweep came, it was clean. Where they died, they generally went *en masse*. The London district was utterly denuded; so was the south and the east of England. The Midland counties were less severely dealt with, and Scotland and Ireland suffered but little. This was the more remarkable, inasmuch as it is a native of a warmer

climate than even the south of England. The facts connected with the wholesale slaughter of 1866 are difficult of explanation. It has been observed that a plant may stand one severe winter and give way to another not so severe, if it occurs within a few seasons after the first. It is as if the vital energy of the plant had sustained a shock which weakened it and left it less able to withstand another. But six years is a long time, and one would have expected that in it the trees might have had time to recuperate from the effects of the winter of 1866. This is not an unprofitable speculation, for *Cupressus macrocarpa* is a tree which it is the interest of every one to preserve amongst us. It is to *Cypresses* what *Pinus insignis* is to the *Pines*. Both are distinguished by their fine Grass-green hue, which gives them a freshness and brightness unequalled in any other *Cypress* or *Pine*. The fine large fruit is well shown in the illustration, although the specimen is a small one. We have seen them nearly twice the size of those figured. The fine slender whip-like shoots of this tree, with their rich red bark, give an attractive elegance to its

Cupressus Lawsoniana.

motion under the breath of the wind. It must not yet be despaired of in Britain; we saw it in great beauty about Edinburgh the other day, and it is to be seen in still greater luxuriance at Castle Kennedy, in Wigtonshire, where a semi-circle of the two varieties, placed in opposition the one to the other, gives every one the opportunity of judging for himself whether they are two species or not. Mr. Fowler, without committing himself to an opinion as to the specific value of the differences, stoutly maintains that whether they be species or varieties, there is a difference by which anyone can refer a plant either to the broad spreading kind or to the taper spire-like form, and there is no disputing the fact that there are two very distinct habits—the one in the line of *Cedrus atlantica*, the other that of the Poplar or *Cupressus torulosa*, which it is impossible to confound in plants belonging to either extreme; but there are often transition plants which it is difficult to refer to one rather than the other, and we observed this even in the group at Castle Kennedy, although it is only right to say that the great majority of plants take either the one habit or the other, and stick to it. In their native country the wide-

spreading kind is the usual form; indeed, we cannot call to mind having seen there any of the fastigate type at all. The

Chamæcyparis (Retinospora) obtusa.

old trees assume some little of the habit of old Cedars of Lebanon, and the young plants are of the broad-spreading fan

Chamæcyparis nutkensis.

shape, showing that they will, ere long, spread out into the broad type of the older ones. In Oakland, the *rus in urbe* of San

Francisco, they are great favourites; and, during the summer, when for months there is no rain, their fresh green (dusty though it be) agreeably relieves the eye. They are planted in every villa garden, and are generally of the above-named type. Seeing that they have escaped our frosts in some parts, and that they have stood very severe cold in many, and only succumbed generally to one winter which may have had some speciality which may not occur again, we think there is no reason why this tree should not be planted freely for decoration. We should not recommend it for commercial purposes, seeing that there are better Cypresses for such, as *C. Lawsoniana*, on whose fitness for our climate there rests no flaw, but for decoration we cannot dispense with it, even although it should be cut down every ten or twenty years. It is even more beautiful in youth than in age. In such a case all we should say would be, "never mind, plant it again."

Cupressus torulosa.

This is a fine dark steeple-like species from the Himalayas, which would be very well worth cultivating if we could be

Cupressus macrocarpa.

sure that it would bear this climate. There are some fine specimens of considerable age and height growing in the south of England, but, speaking of Britain as a whole, we fear to recommend it.

Thujaopsis dolabrata.

We cannot conclude our list of first-class Cypresses without noting one other, which we believe will hereafter be ranked very high as an ornamental shrub or tree. It is the *Thujaopsis dolabrata*, from Japan, and although it has not been long enough cultivated in this country to allow us to be perfectly sure that it will stand all extremities of our climate, our experience, so far as it has gone, encourages us to hope that it will. We see it growing freely in the north of Scotland, as well as all over England. Its chief defect at present seems to be its slow growth. Our expectation is, that it will grow like the shrub-growing specimens of the Hemlock Spruce, only its leaf is twice or thrice as broad, and the broad decided silver marks

beneath are, of course, much more conspicuous. In Japan it grows to be a tree which is described as of great beauty.

Biota orientalis

Although inferior to those in the preceding list, we must not wholly omit the Chinese Arbor-vitæ. It is one type of the Cypress, it is as hard as nails (to use a common expression), and, as a variety in form and colour, is a valuable addition to the others. The American Arbor-vitæ (*Thuja occidentalis*) may be ranked along with it as of equal worth. We place neither of them in the first rank of Cypresses, but very far up in the second.

A. M.

THE DIFFERENT KINDS OF CEANOTHUS.

In this country all the varieties of *Ceanothus* are more or less susceptible of injury from frost, particularly when planted as bushes in open shrubberies. They form, however, magnificent wall-plants, standing in most situations quite hardily; and, from their free growth, handsome foliage, and profusion of bloom, produce the finest possible effects. In all the species the individual flowers are exceedingly small; but this is amply compensated for by their being produced in great masses, coming out in succession during the greater part of the summer, which gives these plants a peculiar importance in garden decoration. As wall-shrubs it is necessary, in order to keep them trim and tidy, that they should be at least annually pruned. This should be done in April, or as soon as danger from serious frost is over; and as all the sorts flower on the shoots of the current year's growth, from one to three eyes of the preceding year's wood should be left, reserving, or at most only topping, such shoots as are required for filling up the open spaces on the wall. All the species are of free growth in ordinary garden soil, if dry, with the sub-soil porous; and they will be found to ripen their wood best and flower most freely in warm sunny exposures. The following are very distinct and desirable:—

C. americanus (the New Jersey Tea).—This plant is interesting from the fact that during the War of Independence the Americans used its leaves as a substitute for tea. It is found in great abundance over a wide area in Canada and the United States as a dwarf deciduous bush from 3 to 4 feet high, and has been known in this country since the beginning of the last century. Though one of the hardest of the species, it thrives best when planted against a wall, or at least in a thoroughly-sheltered situation, and in a dry porous soil. The leaves are about 2 inches long, serrated, and of a bright green colour above, and slightly pubescent beneath. The flowers, which come out in succession from about the middle of June till the end of August, are white, and produced most profusely in axillary panicles.

C. azureus (the Blue-flowered *Ceanothus*) is a sub-evergreen shrub, a native of the temperate regions of Mexico, where it grows as a straggling bush about 10 feet in height, and from whence it was first sent to this country in 1818. It is here one of our most ornamental wall shrubs, flowering as it does, from year to year most abundantly, when planted in a dry, well-sheltered, but sunny situation. The leaves are ovate, serrated, deep green above, and hoary beneath. The flowers, which are borne on large axillary panicles, are bright blue, and are in perfection from June till September, and in mild autumns sometimes till November. The variety of it named *Pallidus*, and in some catalogues *intermedius*, is a handsome companion to the species, between which and *C. americanus* it is said to be a cross; it most resembles *azureus*; the chief differences being its hardier constitution, larger leaves, and flowers of paler blue; in some cases almost white.

C. rigidus (the Rigid *Ceanothus*) is a sub-evergreen, or in mild winters and sheltered situations an evergreen species, discovered by Hartweg in woods near Monterey in California, and sent to this country in 1818. It has an upright habit of growth, rarely exceeding 6 feet in height, the branches stiff and wiry and, in a young state, covered with down. The leaves are very small and profuse, produced on short foot-stalks of a canescent retuse form, dark shiny green above and paler beneath. The flowers, produced in clusters on the sides of the young shoots, are of a deep purple colour, and come out in April and May. It is a pretty free-flowering wall shrub, and worthy of a place in every collection.

C. papillosus (the Pimpled *Ceanothus*).—This very pretty species is indigenous to the mountains of Santa Cruz in California, where it forms a densely branched straggling bush of from 6 to 10 feet. It was first introduced in 1818. Like the other species it requires the protection of a wall, on which it blooms very profusely about June and July. The leaves are small, blunt, dark green above, and slightly downy on the under side. The panicles of pale blue flowers are borne on long foot-stalks from the sides of the young shoots.

C. divaricatus (the Spreading *Ceanothus*).—This fine species was introduced about 1811 from Monterey, where, in sheltered valleys, it is found growing as a dense broad evergreen bush of about 10 feet high. With us it is a free-growing handsome wall-plant, the long slender shoots abundantly clothed with small shining green leaves, being in themselves very attractive. The flowers come out in May, and continue till the frost kills them in autumn; they are of a bright blue colour, and are produced very profusely.

C. dentatus (the Toothed *Ceanothus*).—This elegant small-growing evergreen shrub, rarely found higher than about 3 feet, was sent home from Monterey, in 1818. The leaves are very small, deeply-toothed, of a shining green colour, and abundantly set on the branches. The flowers, which appear in May or June, are deep blue, continuing over the greater part of the season; they are very showy and profuse.

C. verrucosus (the Warted-stemmed *Ceanothus*).—This is another Californian species sent home by Hartweg in 1818. It forms a thickly-branched spreading evergreen bush of about 6 feet in height. As a wall-plant with us it is of remarkably free growth, and has a very fine appearance both as regards foliage and bloom. The leaves are small and blunt, of a bright shiny green. The flowers begin to appear early in May, and continue during the summer months; they are borne in corymbs along the whole length of the young branches, often so profusely as to hide the foliage.—*The Gardener*.

Climbing Shrubs.—Of these some attach themselves to the object they environ by rootlets and suckers, like the Ivy and American Creeper, and these demand no assistance from man to keep them in their places. Others require either nailing to walls or tying up against trellises. Masses of rock or heaps of tree stumps, are best covered by such plants as *Clematis*, *Periploca*, &c., which run rapidly over, and clothe them with a gay livery of elegantly-shaped leaves and masses of flowers. But there are several of these rovers that have the faculty of twining round and round the trunks and branches of trees in the same fashion as the Lianas of tropical forests, where huge trees are stifled by the embrace of these semi-parasites, or, as Gilpin has called them, "these boa-constrictors of sylvan life." There the gigantic coils of luxuriant twiners not only begird and enwrap the tree they grow upon, but they extend their exuberant shoots across towards some other tree, and meeting a rival midway, these entwine round each other till the whole forest becomes matted into one tangled mass. Some of these wild forms of vegetable life might, in a modified and sober way, be reproduced in this country. The *Wistaria*, the *Aristolochia*, the *Menispermum*, the *Trochostigma*, the *Akebia*, and a few other twining shrubs, if planted at the foot of trees of moderate girth in some part of a grove devoted to that purpose, would speedily ascend to the highest part of the trees, and thence wander in search of another victim, till the whole grove became a network of mixed foliage. The trees themselves would not be improved by this, and, therefore, some indifferent plantation should be selected for the experiment. But the result would be a very interesting novelty, and we are, at Heatherside, submitting it to a practical test, by trying the plan on a group of young trees about 20 feet high, with trunks about 6 inches in diameter. Deciduous trees are best fitted for this purpose.—*Heatherside Manual*. [The American Vines are admirably suited for this purpose and were so used with capital effect by the late Dr. Lushington at Oakham.]

NOTES AND QUESTIONS ON TREES AND SHRUBS.

The Whitewashed Bramble (*Rubus biflorus*).—How is it one so seldom sees this peculiarly beautiful plant in private gardens, or grown in an effective manner? What a rich effect might be obtained by associating it on walls with Fresh green Ivy and the scarlet-fruited *Pyracantha japonica* or *Cotoneaster Simmensenii*. Its stems are of snowy whiteness, and if grouped with green and scarlet, would surely assist in making our gardens more bright and cheerful during the dull days of autumn and winter.—B.

The Catalpa (*C. syriacæfolia*).—There are two other species, *Kampferi* and *Bungei*, of little merit compared with this, which is a glorious tree, with splendid foliage and abundant flowers in large bunches, resembling at a distance those of the Horse Chestnut. It is surprising that any garden should be without this noble tree. The variety *aurea* has wonderfully perfect golden leaves, that retain their brilliant colour throughout the season. The growth appears as vigorous as in the common kind.—A. MORGREDEN.

A Fine *Abies nobilis* Uprooted by Wind.—The disastrous gale on the morning of the 21st ult. uprooted a great many trees here, and among them a fine specimen of *Abies (Picea) nobilis*. This tree was 58 feet 1 inch in height; the girth of the stem, at 1 foot up, was 6 feet 6 inches; at 10 feet up, 4 feet 4 inches; at 20 feet up, 3 feet 8 inches; and at 31 feet up, 2 feet 10 inches. This, if not the largest, was probably as fine a specimen of this *Fir* as is to be found in Scotland. It was a grafted plant, and was planted about thirty years ago. A good many fine-looking cones were gathered from it early last month, and we have numbers of trees planted in various parts of this estate raised from seed collected from it in former years.—J. RUSSELL, *Pottulloch, Lushipsh-head*.

THE INDOOR GARDEN.

CARLUDOVICA HUMILIS.

This plant belongs to a small group of Screw Pines, contained in the order Pandanaceae. Some of them have long climbing stems sending out aerial roots, which fasten on the trunks of trees, whilst others have no stems, and form dense low thickets. The genus is confined to tropical south America; and the somewhat Palm-like foliage of these plants forms their most salient distinctive feature. Most of the species form useful subjects as stove plants, but a few of them are sufficiently hardy, it is thought, to endure a lower temperature, even that of an ordinary living room, for a short time, and the experiment might be worth trying. Among those which appear to be of more robust habit than their congeners, may be named the subject of our illustration, *Carludovica humilis*. This is a very compact plant of dwarf growth, with a habit as distinct as possible from the climbing species, though it is furnished with the rudiments of aerial roots. The foliage springs from the apex of a rudimental stem, which is scarcely apparent, and which never rises higher than is shown in the illustration. The fan-like bifurcated and plaited leaves, are developed at the apex of a somewhat long and nearly round stalk, and are of a fine dark green. The flowers, which are incon-

Stemless Screw Pine (*Carludovica humilis*).

spicuous, are monocious. This plant, like all its near relatives, grows in the deep and moist shades of the dense forests of central America. It has been cultivated since 1857, and was first introduced from the Botanic Garden of Berlin. Judging from the situations in which it appears to flourish in its natural state, the more shaded parts of our Palm stoves would suit it best, beneath some of the higher plants. Bog earth, mixed with a portion of marl to give it substance, and yet allow of the free percolation of water, would probably be the best mixture for growing it in in perfection; and there should, of course, be a considerable depth of drainage material. Thus treated, in handsome tubs, or other vessels of pleasing form, it might become a very decorative plant for large living rooms, or halls and staircases, at all events during the summer and autumn. One great advantage of *Carludovica humilis* for such purposes is, that it does not require to be placed near the light, and so impede the view from the windows, as is the case with plants that require to be near the glass. This grand looking plant, on the contrary, may be placed in any dimly lighted corner or niche, where plants of most other classes would rapidly dwindle and perish. Careful experiments testing the sensitiveness of various plants to the influence of light, or its nearly entire absence might prove exceedingly useful. Many Ferns are found to grow more luxuriantly in the semi-darkness of caves, where they only receive a small amount of reflected light. Other plants are only found in the deepest shade of dense forests, and yet the tops of their foliage are not rendered pale by the absence of light. H. N. H.

FRUITING THE EDIBLE PASSION-FLOWER.

The fruit of the *Passiflora*, like that of the Banana, we only see now and then; but it deserves to be far more extensively cultivated as a dessert fruit than it is. *Passiflora quadrangularis* and *P. edulis* are the two varieties best known and appreciated for their fruit. The first is pretty well known as a handsome free-growing stove climber. *P. edulis* possesses the same habit, but its flowers, though chaste and beautiful, are less striking. *P. quadrangularis* produces fruit about the size of a duck's egg, or larger, when the crop is heavy. When ripe, it is of a dull yellow colour, and has an agreeable smell. That of *P. edulis* is seldom much larger than a pigeon's egg, and is of a purplish colour. The rind of both is thick in proportion to the size of the fruit, and encloses a sac containing the seeds and pulp, which is the eatable portion; the flavour of which is agreeable and refreshing. Both varieties bear excessively under ordinarily favourable conditions, though an impression exists that *P. quadrangularis* is difficult to fruit. All that I can say is, that I know scarcely any plant that bears so readily and so abundantly. Some two or three years ago I procured a newly-rooted plant of it in a 3-inch pot about the month of January, which I grew in a Pine stove. During the season it made something like 200 feet of wood, and set about a hundred fruit all at one time, but only half that number attained maturity, weighing each about $\frac{1}{2}$ lb. or more. This was from a plant not twelve months old from a cutting. What it would have been the second year had the plant had room to extend itself, I would not venture to state; but I doubt not it would have been wonderful. The *Passiflora* is not a plant that requires a house for itself; the roof of a plant stove or the back of a Pinery is the place for it; and in such a position it may be made both useful and ornamental. The conditions necessary to secure a vigorous growth and a heavy crop of fruit are abundance of light and air, restricted root room, and a stove temperature both at top and bottom. A stone box, or a large pot, plunged in the corner of the Pine bed or set near the pipes, where the root temperature can be kept at 85° or 90°, is the place for it. Under any circumstances the box should be plunged, otherwise red spider will be troublesome, though the plant is not liable to insect attacks unless it is starved. Good loam and well-rotted manure of any kind will suit it, and plenty of manure-water should be given when the fruit is swelling, especially when the box gets crammed with roots, which it will in a few weeks after the plants get fairly into growth. The shoots may be trained along the wires, about 6 inches apart, and about a foot from the glass. When as many shoots as are needed to fill the allotted space have been obtained, all others which show themselves should be cut clean out. The secret of fruiting *Passiflora* flowers, consists in allowing each shoot that is left to grow on uninterrupted during the season without stopping. The flowers show themselves freely along the shoot as it grows, and they must be fertilised artificially as they expand. If the temperature is kept up to 85° or 90° during the day, and from 70° to 75° at night, and care is taken that the plant does not suffer from want of water at the root, any flower will generally set freely, and the fruit will swell quickly to its full size; but it generally takes from two to three months to ripen. So far as my experience goes, neither young nor old plants show flower until they have made a good bit of growth; it is, therefore, important to start the plant early—say about the beginning of January, increasing the temperature as the days lengthen. At this rate a young plant will flower shortly after Midsummer, and onwards; but an old plant that has some wood about it will fruit considerably earlier. The temperature should be kept well up while the fruit is ripening, otherwise it will be indifferent both in appearance and flavour. *P. edulis* requires the same treatment as *quadrangularis*. J. S. W.

CULTURE OF THE OLEANDER.

NERIUM OLEANDER SPLENDENS and its allies are undoubtedly very magnificent objects when well grown and full of flower; and yet how seldom are they seen in a luxuriant condition, or even seen at all in any shape, except in very few of our gardens? while in France, as well as in other countries, they are grown in large numbers, and in great perfection; not only in large tubs to a great size, as we find them at Versailles and at other places, but in a small and portable shape—small plants, fifteen inches high or so, covered with flowers. In a small state the flowers are not so large as when grown in a planted-out manner, or cultivated in large pots; nevertheless they are very handsome, and last a long while in bloom in healthy rooms or balconies, provided care in watering with tepid water, and washing overhead, occasionally, be persevered in. The Oleander, like every other plant, comparatively speaking, is easily grown and flowered when one knows how. Therefore a few brief instructions to those who do not know how, may be acceptable
